Everyone experiences fatigue occasionally. It is the body's way of signaling its need for rest and sleep. But when fatigue becomes a persistent feeling of tiredness or exhaustion that goes beyond normal sleepiness, it is usually a sign that something more serious is amiss.

Physically, fatigue is characterized by a profound lack of energy, feelings of muscle weakness, and slowed movements or central nervous system reactions. Fatigue can also trigger serious mental exhaustion. Persistent fatigue can cause a lack of mental clarity (or feeling of mental "fuzziness"), difficulty concentrating, and, in some cases, **memory loss**.

Causes and symptoms

Fatigue may be the result of one or more environmental causes such as inadequate rest, improper diet, work and home stressors, or poor physical conditioning, or one symptom of a chronic medical condition or disease process in the body. **Heart disease**, low blood pressure, diabetes, end-stage renal disease,

WWW.BOOKBAZ.IR

iron-deficiency anemia, **narcolepsy**, and cancer can cause long-term, ongoing fatigue symptoms. Acute illnesses such as viral and bacterial infections can also trigger temporary feelings of exhaustion. In addition, mental disorders such as depression can also cause fatigue.

A number of medications, including **antihistamines**, **antibiotics**, and blood-pressure medications, may cause drowsiness as a side effect. Individuals already suffering from fatigue who are prescribed one of these medications may wish to check with their healthcare providers about alternative treatments.

Extreme fatigue which persists unabated for at least six months, is not the result of a diagnosed disease or illness, and is characterized by flu-like symptoms such as swollen lymph nodes, **sore throat**, and muscle weakness and/or **pain**, may indicate a diagnosis of **chronic fatigue syndrome**. Chronic fatigue syndrome (sometimes called chronic fatigue immune deficiency syndrome), is a debilitating illness that causes overwhelming exhaustion and a constellation of neurological and immunological symptoms. An estimated 1.5–2 million Americans suffer from the disorder.

Diagnosis

Because fatigue is a symptom of a number of different disorders, diseases, and lifestyle choices, diagnosis may be difficult. A thorough examination and patient history by a qualified healthcare provider is the first step in determining the cause of the fatigue. A physician can rule out physical conditions and diseases that feature fatigue as a symptom, and can also determine if prescription drugs, poor dietary habits, work environment, or other external stressors could be triggering the exhaustion. Several diagnostic tests may also be required to rule out common physical causes of exhaustion. These may include blood tests to check for iron-deficiency anemia.

Diagnosis of chronic fatigue syndrome is significantly more difficult. Because no specific biological marker or conclusive blood test exists to check for the disorder, healthcare providers must rely on the patient's presentation and severity of symptoms to make a diagnosis. In many cases, individuals with chronic fatigue syndrome go through a battery of invasive diagnostic tests and several years of consultation with medical professionals before receiving a correct diagnosis.

Treatment

Conventional medicine recommends the dietary and lifestyle changes as outlined as a first line of defense against fatigue. Individuals who experience occasional fatigue symptoms may benefit from short-term use of caffeine-containing central nervous stimulants, which make people more alert, less drowsy, and improve coordination. However, these should be prescribed with extreme caution, as overuse of the drug can lead to serious **sleep disorders**, like **insomnia**.

Another reason to avoid extended use of **caffeine** is its associated withdrawal symptoms. People who use large amounts of caffeine over long periods build up a tolerance to it. When that happens, they have to use more and more caffeine to get the same effects. Heavy caffeine use can also lead to dependence. If an individual stops using caffeine abruptly, withdrawal symptoms may occur, including **headache**, fatigue, drowsiness, yawning, irritability, restlessness, **vomiting**, or runny nose. These symptoms can go on for as long as a week.

Alternatives

The treatment of fatigue depends on its direct cause. Several commonly prescribed treatments for non-specific fatigue include dietary and lifestyle changes, the use of essential oils and herbal therapies, deep-breathing exercises, **traditional Chinese medicine**, and color therapy.

DIETARY CHANGES. Inadequate or inappropriate nutritional intake can cause fatigue symptoms. To maintain an adequate energy supply and promote overall physical well-being, individuals should eat a balanced diet and observe the following nutritional guidelines:

- Drink plenty of water. Individuals should try to drink nine to 12 glasses of water a day. Dehydration can reduce blood volume, which leads to feelings of fatigue.
- Eat iron-rich foods (e.g., liver, raisins, spinach, apricots). Iron enables the blood to transport oxygen throughout the tissues, organs, and muscles, and diminished oxygenation of the blood can result in fatigue.
- Avoid high-fat meals and snacks. High-fat foods take longer to digest, reducing blood flow to the brain, heart, and the rest of the body while blood flow is increased to the stomach.
- Eat unrefined carbohydrates and proteins together for sustained energy.
- Balance proteins. Limiting protein to 15–20 grams per meal and two snacks of 15 grams is recommended, but not getting enough protein adds to

fatigue. Pregnant or breastfeeding women should get more protein.

- Get the recommended daily allowance of B complex vitamins (specifically, pantothenic acid, folic acid, thiamine, and vitamin B_{12}). Deficiencies in these vitamins can trigger fatigue.
- Get the recommended daily allowance of selenium, riboflavin, and niacin. These are all essential nutritional elements in metabolizing food energy.
- Control portions. Individuals should only eat when they are hungry, and stop when they are full. An overstuffed stomach can cause short-term fatigue, and individuals who are overweight are much more likely to regularly experience fatigue symptoms.

LIFESTYLE CHANGES. Lifestyle factors such as a high-stress job, erratic work hours, lack of social or family support, or erratic sleep patterns can all cause prolonged fatigue. If stress is an issue, a number of relaxation therapies and techniques are available to help alleviate tension, including massage, **yoga**, **aromatherapy**, **hydrotherapy**, progressive relaxation exercises, **meditation**, and **guided imagery**. Some individuals may also benefit from individual or family counseling or **psychotherapy** sessions to work through stress-related fatigue that is a result of family or social issues.

Maintaining healthy sleep patterns is critical to proper rest. Having a set "bedtime" helps to keep sleep on schedule. A calm and restful sleeping environment is also important to healthy sleep. Above all, the bedroom should be quiet and comfortable, away from loud noises and with adequate window treatments to keep sunlight and streetlights out. Removing distractions from the bedroom such as televisions and telephones can also be helpful.

ESSENTIAL OILS. Aromatherapists, hydrotherapists, and other holistic healthcare providers may recommend the use of essential oils of rosemary (*Rosmarinus officinalis*), eucalyptus blue gum (*Eucalyptus globulus*), peppermint, (*Mentha x piperata*), or Scots pine oil (*Pinus sylvestris*) to stimulate the nervous system and reduce fatigue. These oils can be added to bathwater or massage oil as a topical application. Citrus oils such as lemon, orange, grapefruit, and lime have a similar effect, and can be added to a steam bath or vaporizer for inhalation.

HERBAL REMEDIES. Herbal remedies that act as circulatory stimulants can offset the symptoms of fatigue in some individuals. An herbalist may recommend an infusion of ginger (*Zingiber officinale*) root or treatment with cayenne (*Capsicum annuum*), balmony (*Chelone glabra*), damiana (*Turnera diffusa*), **ginseng** (*Panax ginseng*), or rosemary (*Rosmarinus officinalis*) to treat ongoing fatigue.

An infusion is prepared by mixing the herb with boiling water, steeping it for several minutes, and then removing the herb from the infusion before drinking. A strainer, tea ball, or infuser can be used to immerse loose herb in the boiling water before steeping and separating it. A second method of infusion is to mix the loose herbal preparation with cold water first, bringing the mixture to a boil in a pan or teapot, and then separating the tea from the infusion with a strainer before drinking.

Caffeine-containing, central-nervous-system stimulants such as tea (*Camellia senensis*) and cola (*Cola nitida*) can provide temporary, short-term relief of fatigue symptoms. However, long-term use of caffeine can cause restlessness, irritability, and other unwanted side effects, and in some cases may actually work to increase fatigue after the stimulating effects of the caffeine wear off. To avoid these problems, caffeine intake should be limited to 300 mg or less a day (the equivalent of four to eight cups of brewed, hot tea).

TRADITIONAL CHINESE MEDICINE. Chinese medicine regards fatigue as a blockage or misalignment of *qi*, or energy flow, inside the human body. The practitioner of Chinese medicine chooses **acupuncture** and/or herbal therapy to rebalance the entire system. The Chinese formula Minot Bupleurum soup (or Xiao Chia Hu Tang) has been used for nearly 2,000 years for the type of chronic fatigue that comes after the flu. In this condition, the person has low-grade **fever**, nausea, and fatigue. Additional formulas are helpful in other cases. Acupuncture involves the placement of a series of thin needles into the skin at targeted locations on the body, locations known as acupoints, in order to harmonize the energy flow within the human body.

DEEP-BREATHING EXERCISES. Individuals under stress often experience fast, shallow breathing. This type of breathing, known as chest breathing, can lead to **shortness of breath**, increased muscle tension, inadequate oxygenation of blood, and fatigue. Breathing exercises can both improve respiratory function and relieve stress and fatigue.

Deep-breathing exercises are best performed while laying flat on the back on a hard surface, usually the floor. The knees are bent, and the body (particularly the mouth, nose, and face) is relaxed. One hand should be placed on the chest and one on the abdomen to monitor breathing technique. With proper breathing techniques, the abdomen will rise farther than the chest. The individual takes a series of long, deep breaths through

WWW.BOOKBAZ.IR

the nose, attempting to raise the abdomen instead of the chest. Air is exhaled through the relaxed mouth. Deep breathing can be continued for up to 20 minutes. After the **exercise** is complete, the individual checks again for body tension and relaxation. Once deep breathing techniques have been mastered, an individual can use deep breathing at any time or place as a quick method of relieving tension and preventing fatigue.

COLOR THERAPY. Color therapy, also known as chromatherapy, is based on the premise that certain colors are infused with healing energies. The therapy uses the seven colors of the rainbow to promote balance and healing in the mind and body. Red promotes energy, empowerment, and stimulation. Physically, it is thought to improve circulation and stimulate red blood cell production. Red is associated with the seventh chakra, located at the root; or base of spine. In yoga, the chakras are specific spiritual energy centers of the body.

Therapeutic color can be administered in a number of ways. Practitioners of Ayurvedic, or traditional Indian medicine, wrap their patients in colored cloth chosen for its therapeutic hue. Individuals suffering from fatigue would be wrapped in reds and oranges chosen for their uplifting and energizing properties. Patients may also be bathed in light from a color filtered light source to enhance the healing effects of the treatment.

Individuals may also be treated with color-infused water. This is achieved by placing translucent red colored paper or colored plastic wrap over and around a glass of water and placing the glass in direct sunlight so the water can soak up the healing properties and vibrations of the color. Environmental color sources may also be used to promote feelings of stimulation and energy. Red wall and window treatments, furniture, clothing, and even food may be recommended for their energizing healing properties.

Color therapy can be used in conjunction with both hydrotherapy and aromatherapy to heighten the therapeutic effect. Spas and holistic healthcare providers may recommend red color baths or soaks, which combine the benefits of a warm or hot water soak with energizing essential oils and the fatigue-fighting effects of bright red hues used in color therapy.

Prognosis

Fatigue related to a chronic disease or condition may last indefinitely, but can be alleviated to a degree through some of the treatment options outlined here. Exhaustion that can be linked to environmental stressors is usually easily alleviated when those stressors are dealt with properly.

Chronic fatigue syndrome has no known cure, but steps can be taken to lessen symptoms and improve quality of life for these individuals while researchers continue to seek a cure.

KEY TERMS

Aromatherapy—The therapeutic use of plant-derived, aromatic essential oils to promote physical and psychological well-being.

Guided imagery—The use of relaxation and mental visualization to improve mood and/or physical well-being.

Hydrotherapy—Hydrotherapy, or water therapy, is use of water (hot, cold, steam, or ice) to relieve discomfort and promote physical well-being.

Prevention

Many of the treatments as outlined are also recommended to prevent the onset of fatigue. Getting adequate rest and maintaining a consistent bedtime schedule are the most effective ways to combat fatigue. A balanced diet and moderate exercise program are also important to maintaining a consistent energy level.

Fatty liver

Definition

Fatty liver is the collection of excessive amounts of **triglycerides** and other fats inside liver cells.

Demographics

Fatty liver not due to **alcoholism**, is called non-alcoholic fatty **liver disease** (NAFLD) and affects up to 25–35% of the U.S. population. With an increase in **obesity** in the population over the last 30 years, the incidence of NAFLD has also increased, even affecting about 2.5% of the pediatric population. The prevalence of NAFLD among racial and ethnic groups is not well known, although it is thought to affect both sexes equally.

Severe NAFLD (also called steatohepatitis or NASH) affects 2–5% of Americans, is seen in people 40–60 years old, and is more common in women than men. This form of fatty liver is a leading causes of **cirrhosis** (up to 25%) in adults in the United States.

Fatty liver develops in 90–100% of individuals presenting with heavy alcohol use.

Description

Also called steatosis, fatty liver can be a temporary or long-term condition. The condition is not harmful itself, but may indicate some other type of problem. Left untreated, it can contribute to other illnesses. It is usually reversible once the cause of the problem is diagnosed and corrected. Hard return for new para The liver is the organ responsible for changing fats eaten in the diet to types of fat that can be stored and used by the body. Triglycerides are one of the forms of fat stored by the body and used for energy and new cell formation. The breakdown of fats in the liver can be disrupted by alcoholism, **malnutrition**, **pregnancy**, or **poisoning**. In fatty liver, large droplets of fat, containing mostly triglycerides, collect within cells of the liver. The condition is generally not painful and may go unnoticed for a long period of time. In severe cases, the liver can increase to more than three times its normal size, and may be painful and tender.

Causes and symptoms

The most common cause of fatty liver in the United States is alcoholism. In alcoholic fatty liver, overconsumption of alcohol changes the way that the liver breaks down and stores fats. Often, people with chronic alcoholism also suffer from malnutrition by eating irregularly and not consuming a balanced diet. Conditions that can also cause fatty liver are other forms of malnutrition (especially when there is not enough protein in the diet), obesity, **diabetes mellitus**, and Reye's syndrome in children. Pregnancy can cause a rare, but serious form of fatty liver that starts late in pregnancy and may be associated with **jaundice** and liver failure. Some drug overdoses or toxic chemical poisonings, such as carbon tetrachloride, can also cause fatty liver.

Often, fatty liver carries no symptoms. If symptoms occur, they can include **pain** under the rib cage on the right side of the body, swelling of the abdomen, jaundice, and **fever**. Symptoms that occur less often in alcoholic fatty liver, but more often in pregnancy-related fatty liver, are nausea, **vomiting**, loss of appetite, and abdominal pain.

Diagnosis

During a **physical examination**, a doctor might notice that the liver is enlarged and tender when the abdomen is palpated (examined with the tips of the fingers while the patient lies flat). Blood tests may be used to determine if the liver is functioning properly. A **liver biopsy**, where a small sample of liver tissue is removed with a long needle or though a very small incision, can be used to confirm fatty liver. In pregnant women, the fatty liver condition is usually associated with another serious complication, pre-eclampsia or **eclampsia**. In this condition, the mother has seriously high blood pressure, swelling, and possibly seizures. Laboratory abnormalities include elevations of the SGOT (serum glutamic-oxaloacetic transaminase) and SGPT (serum glutamic pyruvic transaminase). In many cases alkaline phosphatase will be significantly elevated due to **cholestasis** produced by the fatty infiltration.

Treatment

Treatment involves correcting the condition that caused fatty liver and providing supportive care. In fatty liver caused by alcoholism, the treatment is to give up drinking alcohol and to eat a healthy, well-balanced diet. In fatty liver associated with pregnancy, the recommended treatment is to deliver the baby, if the pregnancy is far enough along. Vitamin and mineral supplements along with nutritional support may be useful.

Prognosis

Fatty liver is usually reversible if recognized and treated. Some long-term tendency toward other types of liver problems may exist, depending on how long and how severe the fatty liver condition was. In pregnant women with the condition, the situation can be life-threatening for both the mother and the infant.

WWW.BOOKBAZ.IR

KEY TERMS

Jaundice—A condition in which where the skin and whites of the eyes take on a yellowish color due to an increase of bilirubin (a compound produced by the liver) in the blood.

Reye's syndrome—A serious, life-threatening illness in children, usually developing after a bout of flu or chickenpox, and often associated with the use of aspirin. Fatal cases show evidence of accumulation of fat in the liver.

Triglycerides—A type of fat consumed in the diet and produced by and stored in the body as an energy source.

Left untreated, it results in a high risk of death for both the mother and baby. Severe liver damage that may require a liver transplant can occur in the mother if the condition is not recognized early.

Prevention

Prevention consists of maintaining a well-balanced diet and healthy lifestyle with moderate or no alcohol consumption. Pregnant women require good prenatal care so that symptoms can be recognized and treated as early as possible. To prevent Reye's syndrome, children should not be given **aspirin** to treat symptoms of the flu or other viruses.

Fecal incontinence

Definition

Fecal incontinence is the inability to control the passage of gas or stools (feces) through the anus. For some people fecal incontinence is a relatively minor problem, as when it is limited to a slight occasional soiling of underwear, but for other people it involves a considerable loss of bowel control and has a devastating effect on quality of life and psychological well-being. Fortunately, professional medical treatment is usually able to restore bowel control or at least substantially reduce the severity of the condition.

Description

Fecal incontinence, also called bowel incontinence, can occur at any age, but is most common among people over the age of 65, who sometimes have to cope with **urinary incontinence** as well. It was reported in 1998 that about 2% of adults experience fecal incontinence at least once a week whereas for healthy independent adults over the age of 65 the figure is about 7%. An extensive American survey, published in 1993, found fecal soiling in 7.1% of the surveyed population, with gross incontinence in 0.7%. For men and women the incidence of soiling was the same, but women were almost twice as likely to suffer from gross incontinence.

The wider **public health** impact of fecal incontinence is considerable. In the United States, more than $400 million is spent each year on disposable underwear and other incontinence aids. Fecal incontinence is the second most common reason for seeking a nursing home placement. One-third of the institutionalized elderly suffer from this condition. Incontinence

sufferers, however, often hesitate to ask their doctors for help because they are embarrassed or ashamed. The 1993 American survey discovered that only one-sixth of those experiencing soiling had sought medical advice, and only one-half of those afflicted with gross incontinence.

Causes and symptoms

Fecal incontinence can result from a wide variety of medical conditions, including childbirth-related anal injuries, other causes of damage to the anus or rectum, and nervous system problems.

Vaginal-delivery **childbirth** is a major cause of fecal incontinence. In many cases, childbirth results in damage to the anal sphincter, which is the ring of muscle that closes the anus and keeps stools within the rectum until a person can find an appropriate opportunity to defecate. Nerve injuries during childbirth may also be a factor in some cases. An **ultrasound** study of first-time mothers found sphincter injuries in 35%. About one-third of the injured women developed fecal incontinence or an uncontrollable and powerful urge to defecate (urgency) within six weeks of giving birth. Childbirth-related incontinence is usually restricted to gas, but for some women involves the passing of liquid or solid stools.

The removal of **hemorrhoids** by surgery or other techniques (hemorrhoidectomies) can also cause anal damage and fecal incontinence, as can more complex operations affecting the anus and surrounding areas. Anal and rectal infections as well as Crohn's disease can lead to incontinence by damaging the muscles that control defecation. For some people, incontinence becomes a problem when the anal muscles begin to weaken in midlife or old age.

Dementia, intellectual disabilities (ID), strokes, brain tumors, **multiple sclerosis**, and other conditions that affect the nervous system can cause fecal incontinence by interfering with muscle function or the normal rectal sensations that trigger sphincter contraction and are necessary for bowel control. One study of multiple sclerosis patients discovered that about half were incontinent. Nerve damage caused by long-lasting **diabetes mellitus** (**diabetic neuropathy**) is another condition that can give rise to incontinence.

Diagnosis

Medical assessments in cases of fecal incontinence typically involve three steps: asking questions about the patient's past and current health (the medical history); a **physical examination** of the anal region; and testing for objective information regarding anal and rectal function.

Patient history

The medical history relies on questions that allow the doctor to evaluate the nature and severity of the problem and its effect on the patient's life. The doctor asks, for instance, how long the patient has been suffering from incontinence; how often and under what circumstances incontinence occurs; whether the patient has any control over defecation; and whether the patient has obstacles to defecation in his or her everyday surroundings, such as a toilet that can be reached only by climbing a long flight of stairs. For women who have given birth, a detailed obstetric history is also necessary.

Physical examination

The physical examination begins with a visual inspection of the anus and the area lying between the anus and the genitals (the perineum) for hemorrhoids, infections, and other conditions that might explain the patient's difficulties. During this phase of the examination the doctor asks the patient to bear down. Bearing down enables the doctor to check whether **rectal prolapse** or certain other problems exist. Rectal prolapse means that the patient's rectum has been weakened and drops down through the anus. Next, the doctor uses a pin or probe to stroke the perianal skin. Normally this touching, called the anal wink test, causes the anal sphincter to contract and the anus to pucker; if it does not, nerve damage may be present. The final phase of the examination requires the doctor to examine internal structures by carefully inserting a gloved and lubricated finger into the anal canal. This allows the doctor to judge the strength of the anal sphincter and a key muscle (the puborectalis muscle) in maintaining continence; to look for abnormalities such as **scars** and rectal masses; and to learn many other things about the patient's medical situation. At this point the doctor performs the anal wink test again and asks the patient to squeeze and bear down.

Laboratory tests

Information from the medical history and physical examination usually needs to be supplemented by tests that provide objective measurements of anal and rectal function. Anorectal manometry, a common procedure, involves inserting a small tube (catheter) or balloon device into the anal canal or rectum.

WWW.BOOKBAZ.IR

Among other things, manometry measures pressure levels in the anal canal, rectal sensation, and anal and rectal reflexes. Tests are also available for assessing nerve damage. An anal ultrasound probe can supply accurate images of the anal sphincter and reveal whether injury has occurred. **Magnetic resonance imaging**, which requires the insertion of a coil into the anal canal, is useful at times.

Treatment

Fecal incontinence arising from an underlying condition such as diabetic neuropathy can sometimes be helped by treating the underlying condition. When that does not work, or no underlying condition can be discovered, one approach is to have the patient use a suppository or enema to stimulate defecation at the same time every day or every other day. The goal is to restore regular bowel habits and keep the bowels free of stools. Medications such as loperamide (Imodium) and codeine phosphate are often effective in halting incontinence, but only in less severe cases involving liquid stools or urgency. Dietary changes and exercises done at home to strengthen the anal muscles may also help.

Good results have been reported for **biofeedback** training, although the subject has not been properly researched. In successful cases, patients regain complete control over defecation, or at least improve their control, by learning to contract the external part of the anal sphincter whenever stools enter the rectum. All healthy people have this ability. Biofeedback training begins with the insertion into the rectum of a balloon manometry device hooked up to a pressure monitor. The presence of stools in the rectum is simulated by inflating the balloon, which causes pressure changes that are recorded on the monitor. The monitor also records sphincter contraction. By watching the monitor and following instructions from the equipment operator, the patient gradually learns to contract the sphincter automatically in response to fullness in the rectum. Sometimes one training session is enough, but often several are needed. Biofeedback is not an appropriate treatment in all cases, however. It is used only with patients who are highly motivated; who are able, to some extent, to sense the presence of stools in the rectum; and who have not lost all ability to contract the external anal sphincter. One specialist suggests that possibly two-thirds of incontinence sufferers are candidates for biofeedback.

Some people may require surgery. Sphincter damage caused by childbirth is often effectively treated with surgery, however, as are certain other kinds of incontinence-related sphincter injuries. Sometimes surgical treatment requires building an artificial sphincter using a thigh muscle (the gracilis muscle). At one time a **colostomy** was necessary for severe cases of incontinence, but is now rarely performed.

KEY TERMS

Anus—The opening at the lower end of the rectum.

Colostomy—A surgical procedure in which an opening is made in the wall of the abdomen to allow a part of the large intestine (the colon) to empty outside the body.

Crohn's disease—A disease marked by inflammation of the intestines.

Defecation—Passage of stools through the anus.

Hemorrhoids—Enlarged veins in the anus or rectum. They are sometimes associated with fecal incontinence.

Rectum—The lower section of the large intestine that holds stools before defecation.

Sphincter—A circular band of muscle that surrounds and encloses an opening to the body or to one of its hollow organs. Damage to the sphincter surrounding the anus can cause fecal incontinence.

Stools—Undigested food and other waste that is eliminated through the anus.

Suppository—A solid medication that slowly dissolves after being inserted into the rectum or other body cavity.

Prognosis

Fecal incontinence is a problem that usually responds well to professional medical treatment, even among elderly and institutionalized patients. If complete bowel control cannot be restored, the impact of incontinence on everyday life can still be lessened considerably in most cases. When incontinence remains a problem despite medical treatment, disposable underwear and other commercial incontinence products are available to make life easier. Doctors and nurses can offer advice on coping with incontinence, and people should never be embarrassed about seeking their assistance. Counseling and information are also available from support groups.

Fecal lipids test *see* **Stool fat test**

Fecal occult blood test

Definition

The fecal occult blood test (FOBT) is performed as part of a routine **physical examination** during the examination of the rectum. It is used to detect microscopic blood in the stool and is a screening tool for colorectal cancer. The word "occult" in the test's name means that the blood is hidden from view.

Purpose

FOBT uses chemical indicators on stool samples to detect the presence of blood not otherwise visible. Blood originating from or passing through the gastrointestinal tract can signal many conditions requiring further diagnostic procedures and, possibly, medical treatment. These conditions may be benign or malignant; some of them include:

- colon, rectal, and gastric (stomach) cancers
- ulcers
- hemorrhoids
- polyps
- inflammatory bowel disease
- irritations or lesions of the gastrointestinal tract caused by such medications as nonsteroidal anti-inflammatory drugs, also called NSAIDs
- irritations or lesions of the gastrointestinal tract caused by such stomach acid disorders as reflux esophagitis

The FOBT is used routinely (in conjunction with a **rectal examination** performed by a physician) to screen for colorectal cancer, particularly in patients older than 50. The ordering of this test should not be taken as an indication that cancer is suspected. The FOBT must be combined with regular screening **endoscopy** (such as a **sigmoidoscopy**) to detect cancers at an early stage.

Precautions

Certain foods and medicines can influence the test results. Some fruits contain chemicals that prevent the guaiac, the chemical in which the test paper is soaked, from reacting with the blood. **Aspirin** and some NSAIDs irritate the stomach, resulting in bleeding, and should be avoided prior to the examination. Red meat and many vegetables and fruits containing vitamin C also should be avoided for a specified period of time prior to the test. All these factors could produce a false-positive result.

Description

Feces for the stool samples are obtained either by the physician at the rectal examination or by the patient at home, using a small spatula or a collection device. In most cases, the collection of stool samples can easily be done at home, using a kit supplied by the physician. The standard kit contains a specially prepared card on which a small sample of stool will be spread, using a stick provided in the kit. The sample is placed in a special envelope and either mailed or brought in for analysis. When the physician applies hydrogen peroxide to the back of the sample, the paper will turn blue if an abnormal amount of blood is present.

Types of fecal occult blood tests

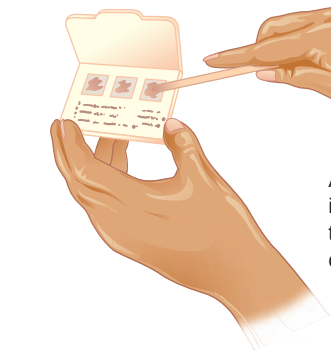
Hemoccult is the most commonly used fecal occult blood test. It measures the presence of heme, an iron-containing pigment found in hemoglobin. The Hemoccult test takes less than five minutes to perform and may be performed in the physician's office or in the laboratory. The Hemoccult blood test can detect bleeding from the colon as low as 0.5 mg per day.

Newer tests that use anti hemoglobin antibodies (or immunochemical tests) to detect blood in the stool are also used. These tests screen for globin, the protein component of hemoglobin, rather than heme. Immunochemical tests can detect up to 0.7 mg of hemoglobin in the stool and do not require dietary restrictions. Immunochemical tests:

- are not accurate for screening for stomach cancer

WWW.BOOKBAZ.IR

How a fecal occult blood test is performed



A small sample of stool is placed on a chemically treated card, pad, or cloth wipe.

Then a special chemical solution is put on top of the sample.

If the card, pad, or cloth turns blue, there is blood in the stool sample.

Conditions that cause the occurrence of blood in the stool include colorectal cancer, hemorrhoids, anal fissures, colon polyps, peptic ulcers, ulcerative colitis, gastroesophageal reflux disease (GERD), and Crohn's disease.

(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

- are more sensitive than Hemoccult tests in detecting colorectal cancer
- are more expensive than Hemoccult tests

HemoQuant, another fecal occult blood test, is used to detect as much as 500 mg/g of blood in the stool. Like the Hemoccult, the HemoQuant test is affected by recent consumption of red meat. It is not affected by chemicals in vegetables.

Fecal blood may also be measured by the amount of chromium in the red blood cells in the feces. The stool is collected for three to 10 days. The test is used in cases where the exact amount of blood loss is required. It is the only test that can exclude blood loss from the gastrointestinal area with accuracy.

A newer fecal occult blood test is based on enzyme immunoassay. This technique does not rely on guaiac, so it is not influenced by diet or medications used prior to the test. The fecal immunoassay test, or FIT, also requires fewer specimen collections. FITs are increasingly replacing the older guaiac-based FOBTs in many settings as of 2014. A 2009 editorial in the *American*

KEY TERMS

Endoscopy—The use of a flexible lighted tube inserted into a body opening to evaluate the internal surfaces of an organ.

Globin—The protein component of hemoglobin. Newer fecal occult blood tests screen for the presence of globin in the stool rather than heme.

Guaiac—A compound derived from the wood resin of guaiacum trees. Guaiac reacts with blood in the stool to produce a blue-colored reaction when peroxide is added to the sample.

Heme—The iron-containing pigment found in hemoglobin.

Hemoglobin—The iron-containing protein found in blood that carries oxygen from the lungs to the rest of the body.

Occult—Not visible or easily detected.

Journal of Gastroenterology urged the use of FITs on the grounds that they do not require patients on blood thinners or NSAIDs to stop taking these medications during stool collection and thereby increase their risk of cardiovascular problems.

Two tests are based on DNA analysis of stool samples for biological markers of colorectal cancer. The first test of this type, PreGen-Plus, was first used in 2004 but held up for widespread distribution by a warning letter from the U.S. Food and Drug Administration (FDA) in October 2008. ColoSure, a DNA test that measures only one biomarker for colorectal cancer, was made available in the summer of 2008. It retails for about $220. ColoSure is not as accurate as a **colonoscopy** but is less invasive and is intended to be used for patients who resist having a colonoscopy. Widespread use of these new tests remains to be seen. As of 2014, the newer DNA stool tests appear to be cost-effective only in patients who are not compliant with other screening methods for colorectal cancer.

Over-the-counter (OTC) fecal occult blood test kits are now available for purchase at most pharmacies in the United States and Canada. These tests, however, are not as reliable as those performed in doctors' offices or laboratories.

Preparation

For 72 hours prior to collecting samples, patients should avoid red meats, NSAIDs (including aspirin), **antacids**, **steroids**, iron supplements, and vitamin C, including citrus fruits and other foods containing large amounts of vitamin C. Foods like uncooked broccoli, uncooked turnips, cauliflower, uncooked cantaloupe, uncooked radish and horseradish, and parsnips should not be eaten during the 72 hours prior to the examination. Fish, chicken, pork, fruits (other than melons) and many cooked vegetables are permitted in the diet.

People should postpone an FOBT if they are presently having **diarrhea**, **constipation**, a flare-up of **hemorrhoids**, severe **sore throat**, or a menstrual period.

Results

Many factors can result in false-positive and false-negative findings.

Positive results

It is important to note that a true-positive finding signifies only the presence of blood—it is not an indication of cancer. The National Cancer Institute states that, in its experience, less than 10% of all positive results were caused by cancer. The FOBT is positive in 1–5% of the unscreened population and 2–10% of those are found to have cancer. The physician will want to follow up on a positive result with further tests, as indicated by other factors in the patient's history or condition.

Negative results

Alternatively, a negative result (meaning no blood was detected) does not guarantee the absence of **colon cancer**, which may bleed only occasionally or not at all. (Only 50% of colon cancers are FOBT-positive.)

Conclusions

Screening using the FOBT has been demonstrated to reduce the mortality associated with colorectal cancer. However, because only half of colorectal cancers are FOBT-positive, FOBT must be combined with regular screening endoscopy or colonoscopy to increase the accuracy of detection of premalignant colorectal polyps and cancers.

Fecal transplant

Definition

A **fecal transplant** is the transfer or transplantation of bacteria from the feces of a healthy human into the intestines of a patient with a digestive disorder—most often an antibiotic-resistant *Clostridium difficile* infection or CDI. It is often referred to as fecal transplantation or more correctly as fecal microbiota transplantation (FMT).

Earlier terms for this procedure include fecal bacteriotherapy, stool transplant, fecal enema, and fecal infusion, but these are now considered obsolete. FMT is considered the definitive term as of 2014 and will be used throughout the remainder of this entry.

Description

Fecal microbiota transplantation (FMT) involves the infusion of bacteria from the feces of a healthy human donor into the intestines of a patient suffering from CDI or such other digestive disorders as ulcerative **colitis**. The reasoning behind FMT is that replacing harmful bacteria like *C. difficile* with harmless organisms that ordinarily live in the gut will restore the patient's colon to a healthy state.

FMT begins with preparation of an infusion containing fecal bacteria from a healthy donor. A genetic relationship between donor and patient is not necessary, but the physician will often ask a relative or friend of the patient to donate a stool sample if it is convenient. The stool sample is then rigorously tested for bacterial or parasitic infections. If none are found, the sample is mixed with sterile saline solution and infused into the patient by one of three methods: an enema, infusion via a colonoscope, or infusion into the upper gastrointestinal tract via a **nasogastric tube**. The enema method is considered the simplest. All three methods, however, appear to be equally effective. *C. difficile* infections usually require only one infusion whereas patients with ulcerative colitis typically require several.

Some hospitals store samples from known healthy donors in a freezer, to be thawed and used when needed. Since 2012, OpenBiome, a startup nonprofit headquartered in Massachusetts, has been offering screened, filtered, and frozen fecal infusions ready for clinical use. Another option, still considered experimental, is for a patient concerned about the possibility of developing a *C. difficile* infection as a complication of antibiotic therapy to store a sample of his or her own stool prior to receiving the antibiotic. This approach is known as autologous restoration of gastrointestinal flora or ARGF.

Purpose

The purpose of FMT is to restore the normal bacterial flora in the patient's intestines in order to cure CDI, whose symptoms can include **diarrhea**, bloating, abdominal cramping, and pseudomembranous colitis (diarrhea and flu-like symptoms) caused

by *C. difficile* infection or CDI. *C. difficile* is a spore-forming bacterium that is capable of overrunning the digestive tract when the normal bacteria are eliminated, often by antibiotic treatment for an unrelated infection. When *C. difficile* multiplies without competition from the normal bacteria, it releases toxins that cause bloody diarrhea and other symptoms of CDI. While mild cases of CDI sometimes can be treated by discontinuing the antibiotic that was administered prior to the onset of the disorder, more severe cases of CDI require either a strong antibiotic such as vancomycin or metronidazole, or FMT. FMT has been found to be far more effective (with a cure rate between 90% and 94%) than vancomycin, as well as much less expensive. As of 2014, FMT is being used to treat children as well as adults with CDI.

CDI has become a serious problem in North America since 2000, as some strains of *C. difficile* have become antibiotic-resistant and others have become far more virulent. The number of cases of CDI has increased dramatically since 2000; the number of cases among hospitalized adults tripled between 1993 and 2005 and more than doubled again between 2001 and 2005. As of 2014 there are 300,000 cases of hospital-acquired CDI in the United States each year and as many as 2,500,000 cases developing outside hospitals. About 14,000 patients die each year in North America as a result of fulminant CDI. Because of the dramatic effectiveness of FMT in treating CDI, some experts are calling for it to be considered first-line therapy in place of vancomycin and metronidazole. In 2013, the Food and Drug Administration (FDA) held a workshop for researchers and clinicians on FMT, and the American College of Gastroenterology (ACG) added FMT to its treatment guidelines for CDI.

Although FMT is presently approved only for the treatment of *C. difficile* infection, it is also used to treat ulcerative colitis, although several infusions are usually necessary before this disorder responds to the therapy. Researchers are investigating the usefulness of FMT to treat nondigestive disorders, including **autoimmune disorders**, **multiple sclerosis**, Parkinson's disease, **obesity**, and diabetes, but the approach is still considered an experimental therapy for these disorders.

Preparation

Fecal microbiota transplantation is usually administered in a hospital. No special preparation on the patient's part is required.

KEY TERMS

Flora—The collective bacteria in the intestines or other part of humans and other animals.

Fulminant—Referring to any medical event that develops quickly and explosively, and is severe and potentially lethal. The English word comes from the Latin word for lightning.

Infusion—A medical treatment in which liquid substances are delivered into the body through various routes of administration.

Microbiota—The collection of microorganisms that live in the human body (or another ecological niche) taken as a whole.

Pseudomembranous colitis—Infection of the large intestine that presents with infectious diarrhea and flu-like symptoms.

Ulcerative colitis—A form of disease that results in ulcers in the colon.

Aftercare

The patient can usually go home within six to 24 hours following the infusion. Patients with severe relapsing or fulminant CDI are usually kept overnight for observation. A stool sample is taken from the patient several days later and tested to confirm that the CDI has been eradicated.

Results

The results of FMT for *C. difficile* infection are almost always complete cure of the infection. The Mayo Clinic's findings are typical: a 90% cure rate after the first infusion, with another 8% of patients cured after the second infusion. Relapsing CDI is rare following FMT. As of 2014, no transmissions of infection have been reported in over 370 published cases.

Risks

Researchers and clinicians have noted several risks with FMT, the most worrisome being the possibility that the donated stool sample might transmit an infectious organism despite having been tested. In addition, the use of a colonoscope or nasogastric tube always carries some risk of damage to tissues. Last, the use of FMT is contraindicated in the following groups of patients:

- people who are taking immunosuppressant drugs

WWW.BOOKBAZ.IR

- people who have had a recent bone marrow transplant
- people who have a concurrent digestive disorder
- people with HIV infection or AIDS
- people with cirrhosis of the liver

Feldenkrais method

Definition

The Feldenkrais method is an educational system that allows the body to move and function more efficiently and comfortably. Its goal is to re-educate the nervous system and improve motor ability. The system can accomplish much more, relieving pressure on joints and weak points, allowing the body to heal repetitive strain injuries. Continued use of the method can relieve **pain** and lead to higher standards of achievement in sports, the martial arts, dancing, and other physical disciplines.

Pupils are taught to become aware of their movements and to become aware of how they use their bodies, thus discovering possible areas of **stress** and strain. The goal of Feldenkrais is to take the individual from merely functioning, to functioning well, free of pain and restriction of movement. Feldenkrais himself

MOSHE FELDENKRAIS (1904–1984)

Moshe Feldenkrais was born on the border between Russia and Poland. When he was only a boy of 13, he traveled to Palestine on foot. The journey took a year, and once there, young Feldenkrais worked as a laborer and cartographer, also tutoring others in mathematics. Moving to France in 1933, he graduated in mechanical and electrical engineering from the Ecole des Travaux Publiques de Paris.

Feldendrais became the first person to open a Judo center in Paris after meeting with Jigaro Kano. He was also one of the first Europeans to become a black belt in Judo, in 1936.

Obtaining his PhD at the Sorbonne, he went on to assist Nobel Prize laureate Frédéric Joliot-Curie at the Curie Institute. During World War II in England, he worked on the new sonar anti-submarine research.

Prompted by a recurring leg injury, he applied his knowledge of the martial arts and his training as an engineer to devise a method of re-integrating the body. The concept was that more efficient movement would allow for the treatment of pain or disability, and the better-functioning of the body as a whole. Later on, he would begin to teach what he had learned to others in Tel Aviv.

In addition to many books about judo, including *Higher Judo*, he wrote six books on his method.

stated that his goal was, "to make the impossible possible, the possible easy, and the easy, elegant."

Purpose

This method of re-educating the nervous system can be beneficial to a wide range of people, including athletes, children, the elderly, martial artists, those who are handicapped, people with special needs, and those with degenerative diseases. It has proved popular with artists, particularly musicians, a number of whom have used Feldenkrais to improve their performance.

The Feldenkrais Guild of North America (FGNA) states that more than half of the those who turn to Feldenkrais practitioners are seeking relief from pain. Many people who have pain from an injury compensate by changing their movements to limit pain. Often these changed movements remain after the pain from the original injury is gone, and new pain may occur. Feldenkrais helps students become aware of the changed movements and allows them to learn new movements that relieve their pain.

Apart from the obvious physical benefits of more efficient movement and freedom from pain and restriction, Feldenkrais practitioners assert that it has other positive benefits for overall physical and mental health, including increased awareness, flexibility, and coordination, and better relaxation. Feldenkrais practitioners have noted other benefits in their students, including improvements in awareness, flexibility, coordination, breathing, digestion, sleep, mood, mental alertness, energy, and range of motion, as well as reduced stress and **hypertension**, and fewer headaches and backaches.

Musicians and athletes can improve their performance in many ways when they learn to use their bodies more efficiently. Feldenkrais can help injured athletes regain lost potential and free them from pain and restriction of movement.

Numerous accounts note remarkable results when Feldenkrais is taught to handicapped children so that they can learn to function despite their limitations. Handicapped people can learn to make full use of whatever potential they have, and to have more confidence in their abilities. Practitioners who specialize in teaching Feldenkrais to those who have handicaps have in many cases allowed the patient to discover ways of performing tasks that were previously thought to be impossible for them.

The elderly, whose movements are often restricted by pain and stiffness, can learn to overcome these obstacles with Feldenkrais instruction. In some instances, even severe cases of arthritis have been conquered. Theoretically, Feldenkrais can make possible renewed levels of energy and freedom from restriction.

Description

Origins

Moshe Feldenkrais (1904–1984) was a Russian-born Israeli physicist and engineer who was also an active soccer player and judo master. He devised his system in response to his own recurring knee injury, which had restricted his movement and caused him great pain over a long period of time. Feldenkrais believed that repeated muscle patterns cause the parts of the brain controlling those muscles to stay in a fixed pattern as well. He thought that the more the muscles are used, the more parts of the brain can be

WWW.BOOKBAZ.IR

activated. He devised a method of re-educating the neuromuscular system and re-evaluating movement to increase efficiency and reduce stress, using his knowledge of mechanics and engineering, and applying some of his martial arts training.

Feldenkrais is described as being a dual system, with two components: "Awareness Through Movement" and "Functional Integration." The system aims to re-educate the body so that habitual movements that cause strain or pain can be relearned to improve efficiency and eliminate dangerous or painful action.

Feldenkrais helps to translate intention into action. In practice, an individual can learn to achieve his or her highest potential, while at the same time learning to avoid and eliminate stresses, strains, and the possibility of injury.

Functional integration

During this session, the patient wears comfortable clothing, and may sit, stand, walk, or lie on a low padded table. The practitioner helps the pupil by guiding him or her through a number of movements. The practitioner may use touch to communicate with the student, but touch is not used to correct any movements. The purpose of this session is to increase a student's awareness of his or her own movement and become open to different possibilities for movement. The instruction can be focused on a particular activity that the student does every day, or that causes him or her pain. The student can learn to alter habitual movements and re-educate the neuromuscular system. This type of session is particularly useful for those who have limitations originating from misuse, stress, illness, or accident. It can also help athletes and musicians perform to the best of their ability by increasing their possibilities for movement. It offers students the potential for improving their physical and mental performance in addition to heightening the sense of well-being.

Awareness through movement

Feldenkrais's martial arts background can be clearly identified in many of the aspects of Awareness Through Movement (ATM). During group sessions, pupils are taught to become acutely aware of all their movements and to imagine them, so that they can improve the efficiency of their actions in their minds, and put them into practice. Pupils are encouraged to be disciplined about practicing their exercises so they may achieve maximum benefit.

KEY TERMS

Neuromuscular—The body system of nerves and muscles as they function together.

Repetitive strain injury—Injury resulting from a repeated movement such as typing or throwing a ball.

Awareness through movement is described as an exploratory, nonjudgmental process through which pupils are encouraged to observe and learn about themselves and their movements. The range of this therapy is wide, and thousands of different lessons are available to help specific areas.

Preparations

No preparation is necessary for the practice of Feldenkrais, and all are encouraged to seek help from this system. No condition is considered a preclusion to the benefits of Feldenkrais.

Risks

As with any therapy or treatment, care should be taken to choose a qualified practitioner. Feldenkrais practitioners stress that the body must not be forced to do anything, and if any movement is painful, or even uncomfortable, it should be discontinued immediately and the patient should seek professional help.

No known side effects are associated with the practice of Feldenkrais.

Results

Since Feldenkrais began to teach his method, it has gradually gained acceptance as an education system. Published research using the method can be found in United States and foreign publications.

Female genital mutilation

Definition

Female genital mutilation (FGM)—also called female genital cutting (FGC) or female circumcision—is the cutting or partial or total removal of the external female genitalia. It is performed for cultural or other non medical reasons, most often on girls between the ages of four and 10.

Demographics

The World Health Organization (WHO) estimates that between 100 million and 140 million girls and women have undergone some form of FGM, with as many as three million girls at risk for the procedure each year. FGM is a deeply rooted cultural tradition in some 28 African countries and a few Middle Eastern and Asian nations. Although it is illegal in many countries, including 18 African nations, enforcement is minimal. In the United States it is illegal to perform FGM on anyone under age 18.

Nearly half of all women who have been genitally mutilated live in Egypt or Ethiopia, although the rates of FGM in Egypt and some other countries appear to be on the decline. FGM is practiced to a lesser degree in Indonesia, India, and Pakistan. The countries in which the highest percentages of females are subjected to FGM are as follows (where two percentages are given, the lower percentage refers to girls aged 15–19 and the higher percentage is for women aged 35–39, suggesting that the practice is on the decline):

- Guinea: 99%
- Somalia: 97–99%
- Djibouti: 98%
- Egypt: 81–96%
- Eritrea: 95%
- Mali: 94%
- Sierra Leone: 90%
- Ethiopia: 62–81%
- Gambia: 80%
- Côte d'Ivoire: 28–44%
- Kenya: 15–35%

FGM is practiced by people of all educational levels and social classes and various religions, including Christians, Muslims, and animists. In some countries it is more common in rural areas and in other countries it is more prevalent in cities.

Although FGM is most often performed on girls before they reach **puberty**, it is practiced on women of all ages, from infancy through adulthood. The usual age for FGM varies with the country and region within a country. Sometimes it is performed just before a woman marries or during her first **pregnancy**. In Egypt about 90% of girls are cut between the ages of four and 12. In Yemen more than 75% of girls are cut during the first two weeks of life. In Burkina Faso, Côte d'Ivoire, Egypt, Kenya, and Mali, the age for FGM is decreasing, perhaps because younger children are less able to resist or because in countries where it is illegal, the practice is more easily concealed with younger girls.

Description

FGM includes a wide range of procedures. The simplest form of FGM involves a small cut to the clitoris or labial tissue. A Sunna **circumcision** removes the prepuce—a fold of skin that covers the clitoris—and/or the tip of the clitoris. A clitoridectomy is the removal of the entire clitoris and some or all of the surrounding tissue. Clitoridectomies account for approximately 80% of FGMs. The most extreme form of genital mutilation is excision and infibulation, in which the clitoris and all of the surrounding tissues of the external genitalia are cut away and the remaining skin is sewn together, leaving only a small opening for the passage of urine and menstrual blood. This sewing shut of the vagina is designed to ensure virginity until marriage. Infibulation accounts for approximately 15% of FGM procedures.

WWW.BOOKBAZ.IR

FGM is usually performed in the home or some other non medical setting. Often it is performed by a family member or a local "circumciser," using scissors, knives, razor blades, or other instruments that have not necessarily been sterilized. However in Egypt up to 90% of FGMs are now performed by medical professionals.

With increased immigration to Western countries from regions where female circumcision is common, the practice has come to the attention of health professionals in the United States, Canada, Europe, and Australia. Some families return to their native countries to have their daughters circumcised. In an effort to integrate old customs with modern medical care, some immigrant families have requested that Western physicians perform the procedure. This can place doctors in the difficult position of trying to be sensitive to cultural traditions and choosing between performing female circumcision in a medical facility under **anesthesia** and sanitary conditions or refusing, knowing that the FGM may be performed without medical supervision. In 2010 the American Academy of Pediatrics, in a controversial change of policy, suggested that U.S. doctors be allowed to perform a ceremonial pinprick on girls to prevent them from being sent abroad for FGM.

Causes and symptoms

FGM is practiced for a variety of cultural, social, political, and economic reasons:

- FGM is usually an integral part of community tradition.
- Most parents believe that genital cutting protects—rather than harms—their daughters.
- In some cultures FGM is considered a necessary rite of passage for girls and may even mark their introduction to sexual activity.
- Although FGM represents social and cultural control of female sexuality, some cultures believe that FGM actually empowers women by protecting their family's reputation and ensuring that they will marry.
- Female circumcision is believed to protect a girl's virginity and prevent unwed pregnancy, which could bring shame upon the family.
- In some cultures uncircumcised females are considered to be dirty or unmarriageable and may be treated poorly.
- In some societies FGM is believed to quell female sexual desire.
- Some people believe that their religion requires female circumcision.
- Some people believe in superstitions—that the clitoris will continue to grow if it is not removed or that external genitalia are unclean and can kill an infant during birth.

The effects of FGM depend on the degree of cutting, the cleanliness of the instruments, and the health of the female at the time of the procedure. FGM is usually performed without anesthesia and almost always causes bleeding and **pain**. The pain is usually most severe on the following day when the patient first urinates onto the wound.

The immediate risks of FGM include:

- physical and/or psychological trauma
- hemorrhage (excessive bleeding)
- severe pain
- infection, including abscesses, fever, sepsis (blood infection), shock, tetanus, or gangrene
- death due to excessive blood loss or infection

Long-term complications usually occur with the more severe forms of FGM and include:

- scarring
- poor drainage of urine and menstrual blood, leading to infection
- chronic urinary tract infections
- cysts and abscesses
- incontinence
- pelvic and back pain
- painful menstruation
- very painful sexual intercourse due to scarring of most of the vagina
- lack of sexual pleasure
- inability to undergo normal gynecological exams and procedures
- increased risk for sexually transmitted infections (STIs), including HIV/AIDS, both from contaminated instruments and also because the damaged tissues are more likely to tear during sex, facilitating the transmission of infectious agents
- infertility rates as high as 25–30%, usually related vaginal scarring that makes sexual intercourse difficult
- childbirth complications, including prolonged labor, tearing, heavy bleeding, and infection
- psychological symptoms similar to post-traumatic stress syndrome (PTSD), including anxiety, depression, and sleep abnormalities, although these conditions are rare

KEY TERMS

Circumcision—A procedure, usually with religious or cultural significance, in which the prepuce—the skin covering the tip of the male penis or the female clitoris—is cut away.

Clitoridectomy—A procedure in which the clitoris and possibly some of the surrounding labial tissue at the opening of the vagina is removed.

Clitoris—The small erectile organ at the front of the female vulva that is the site of female sexual pleasure.

Infibulation—A procedure that closes the labia majora to prevent sexual intercourse, leaving only a small opening for the passage of urine and menstrual blood.

Labia majora—The outer fatty folds of the vulva.

Prepuce—The fold of tissue covering the clitoris in females and the tip of the penis in males.

Vulva—The external female genital organs, including the labia majora, labia minora, clitoris, and vestibule of the vagina.

Diagnosis

Diagnosis and treatment of FGM requires the care of culturally sensitive gynecologists and women's healthcare specialists who are familiar with the different types of FGM and their complications.

Treatment

A girl or young woman who has recently had FGM may require supportive care to control bleeding. Treatment may be necessary for any complications. Women who have undergone FGM may require specialized gynecologic, obstetric, and reproductive care by knowledgeable practitioners.

In the United States female immigrants with FGM often undergo defibulation or **reconstructive surgery** to reverse or repair their genitalia. Some surgical procedures that were originally developed for sex–change operations have been adapted for treating women with FGM. These techniques may involve cutting away scar tissue and skin to expose whatever remains of the clitoris, as well as more extensive reconstruction.

Drugs

Females who have recently undergone FGM may require **antibiotics** to prevent infection.

Prognosis

FGM can adversely affect a woman's quality of life, particularly with regard to sexual enjoyment and **childbirth**. FGM is associated with postpartum hemorrhage, **episiotomy**, extended hospital stays, **stillbirth**, infant resuscitation, and infant and maternal death. Circumcised pregnant women sometimes must deliver by Caesarian section.

Prevention

Many national and international medical organizations—including the American Medical Association, Canadian medical associations, and the World Health Organization (WHO)—oppose the practice of female genital mutilation. The United Nations considers FGM to be a violation of human rights and several African and Asian nations have called for an end to the practice. WHO has undertaken a number of projects aimed at decreasing the incidence of FGM. These include:

- a statement addressing the regional status of FGM and encouraging the development of national policies against the practice
- training community workers to oppose FGM
- developing educational materials about FGM for community healthcare workers
- providing alternative job training for circumcisers

Other approaches to halting the practice of FGM include:

- community meetings, discussions, theater productions, and songs
- educational programs conducted by respected local women
- work by Islamic and other religious leaders to change the perception that FGM is required by religion
- substitution of other coming-of-age rituals for girls
- laws prohibiting FGM except as the free choice of an adult woman

Female orgasmic disorder

Definition

Female orgasmic disorder (FOD) is the persistent or recurrent inability to achieve orgasm (climax or sexual release) despite adequate sexual arousal and stimulation. FOD is also called orgasmic dysfunction or anorgasmia. It used to be called "inhibited sexual orgasm."

Demographics

The inability to achieve orgasm, discontent with the quality of orgasms, and the ability to achieve orgasm only with a particular type of sexual stimulation are very common sexual complaints among women. It has been suggested that 33–50% of all women are dissatisfied with the frequencies of their orgasms and that fewer than one-third of women consistently experience orgasm with sexual activity. However FOD applies to the 10–15% of women have never experienced an orgasm, regardless of the situation or stimulation, and to women who can no longer achieve an orgasm. Women who have never experienced orgasm are more likely to be unmarried, young, and/or sexually inexperienced. FOD has also been associated with **menopause** and **aging**, although many women find that their orgasms increase with age.

Description

When a woman becomes sexually excited, the blood vessels in the pelvic region expand, allowing more blood to flow to the genitals—the same process that occurs when men become sexually excited. This effusion is followed by seepage of fluid into the vagina to provide lubrication before and during intercourse. These events are called the "lubrication–swelling response."

Body tension and blood flow to the pelvic region continue to build as sexual stimulation increases, either by direct pressure on the clitoris or pressure on the walls of the vagina and cervix. An orgasm occurs when the tension is released. It is accompanied by a feeling of intense physical pleasure and involuntary, rhythmic contractions of the pelvic floor muscles and possibly the vagina and uterus. The contractions carry blood away from the genital region. However the exact physiological mechanisms of the female orgasm are not well-understood. Furthermore, women do not necessarily experience orgasms in the same way, and an individual woman may experience orgasms differently at various times and in different situations.

Orgasms vary in intensity, length, and the number of contractions, and, unlike men, women can have multiple orgasms in a short period of time. Some 50–80% of women experience orgasm only through direct clitoral stimulation. Mature, more sexually experienced women may find it easier to have orgasms than younger or sexually inexperienced women.

FOD is a type of **sexual dysfunction** that affects the quality of a woman's sexual experience. It often occurs in conjunction with other sexual dysfunctions. Women with FOD experience sexual arousal and lubrication. However as body tension builds, they have extreme difficulty or are completely unable to reach climax and release the tension. This can lead to frustration and less-than-fulfilling sexual experiences for both partners, as well as anger, frustration, and other relationship problems.

According to the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders,* the *DSM,* a diagnosis of FOD requires that the anorgasmia is not due solely to physiological problems and is not a symptom of another major mental health disorder. However FOD can be caused by a combination of physiological and psychological difficulties. For a diagnosis of FOD the condition also must cause personal distress or relationship problems.

FOD is most often a primary or lifelong condition, in which women never achieve orgasm with any type of stimulation, including self-stimulation (masturbation), direct stimulation of the clitoris by a partner, or vaginal intercourse. Secondary or acquired FOD affects women who have experienced orgasm at least once in the past, but have lost the ability following an illness or emotional **trauma** or as a side effect of surgery or medication. Acquired FOD is often temporary. Anorgasmia may also be classified as general, which means that orgasm is never achieved under any circumstances or with any partner; or situational, which means that orgasm is only achieved under certain circumstances or with certain types of sexual activity.

Risk factors

Recent studies of twins suggest that genes and heredity play a large role in the development of FOD. A history of sexual or physical **abuse** is also a risk factor for FOD.

Causes and symptoms

FOD is characterized by a woman's inability to achieve orgasm, by extreme difficulty in regularly reaching climax, or having only unsatisfying orgasms. Some women often come close to orgasm but never reach it. FOD can be caused by psychological factors or by a combination of psychological and physiological factors.

Psychological causes of FOD include:

- feelings of isolation, disconnection, or boredom during sex
- shyness or embarrassment
- performance anxiety or sexual activity that is overly goal-oriented, with excessive pressure to achieve orgasm
- past sexual or physical abuse, rape, incest, or other traumatic sexual experiences
- emotional abuse
- fear of pregnancy
- fear of rejection
- fear of loss of control during orgasm
- self-image problems
- relationship problems
- life stresses, such as financial worries, job loss, or divorce
- guilt or negative feelings toward sex or sexual pleasure—attitudes that are usually learned in childhood or adolescence
- religious or cultural beliefs about sex
- other mental health disorders, such as major depression

Various prescription and over-the-counter medications can cause aorgasmia. These include:

- antidepressants called selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine (Prozac), paroxetine (Paxil), and sertraline (Zoloft)
- anti-anxiety drugs such as Xanax
- sedatives such as Halcion
- narcotics
- antihistamines
- blood-pressure medications
- chemotherapy drugs

Other physiological causes of FOD include:

- inadequate sexual stimulation and the inability to discuss or explore more stimulating sexual techniques
- lower estrogen levels during and after menopause, which reduce lubrication and require greater stimulation for relaxing and promoting blood flow to the clitoris and vagina
- other normal aging processes
- smoking, alcohol, or other substance abuse
- hormonal disorders and chronic illnesses that affect general health and sexual interest

WWW.BOOKBAZ.IR

KEY TERMS

Anorgasmia—A sexual dysfunction characterized by the inability to achieve orgasm.

Clitoris—The small erectile organ at the front of the female vulva that is the site of female sexual pleasure.

Estrogen—Any of several naturally occurring or synthetic steroid hormones that promote the growth and maintenance of the female reproductive system.

Kegel exercises—Repetitive contractions to tone the pubococcygeal muscle for enhancing sexual response during intercourse or controlling incontinence.

Orgasm—The climax of sexual excitement, usually characterized by vaginal contractions by the female and ejaculation of semen by the male.

Testosterone—The primary male sex hormone, which is also produced at low levels in females.

- damage to the blood vessels of the pelvic region
- conditions that affect or damage pelvic nerves, including pelvic surgery, multiple sclerosis, diabetes, neurological disease, or spinal cord injury
- pelvic floor prolapse—a loosening of the muscles that support internal pelvic organs
- removal of the clitoris (female genital mutilation), a cultural practice in much of Africa and some regions of the Middle East and Asia

Diagnosis

FOD is often self-diagnosed. However a woman who has never had an orgasm may not realize what is missing in her sexual experience without diagnosis by a physician, women's healthcare specialist, psychiatrist, psychologist, or sex therapist.

Examination

Diagnosis of FOD includes a complete physical exam and medical, psychological, and sexual histories. The clinician or therapist helps determine whether the problem is primary or acquired and general or situational. FOD sometimes occurs in conjunction with sexual aversion disorder and/or **female sexual arousal disorder**, complicating the diagnosis. A diagnosis of FOD requires that:

- Orgasms occur less frequently than would be expected based on the patient's age, sexual experience, and level of sexual stimulation.
- The absence of orgasm results in emotional distress or relationship difficulties.
- The cause is psychological or a combination of psychological and physical factors.
- The absence of orgasm is not a symptom of another psychological disorder, such as depression.

Tests

Blood tests may be performed to measure the levels of estrogen and testosterone.

Treatment

Treatment of FOD requires addressing any underlying physiological causes, psychological factors such as depression, and lifestyle factors such as substance abuse. Medications may require adjustment. Any associated sexual dysfunctions, such as lack of interest in sex or painful intercourse, must also be addressed. FOD is commonly treated with education, counseling, cognitive-behavioral therapy, **psychotherapy**, and/or **sex therapy**.

Psychotherapy or counseling can be effective for treating psychological causes of FOD, especially those causes that are rooted in **sexual abuse**, past sexual or emotional experiences, or cultural taboos. Couples therapy may be used to resolve relationship issues that have either caused or resulted from FOD. These processes require time and a joint commitment by couples.

Sex therapists have specialized training for assisting individuals and couples in overcoming sexual dysfunctions. Sex therapy may include:

- directed exercises for increasing stimulation and decreasing inhibitions
- techniques for relaxation, sexual exploration, and direct clitoral stimulation
- encouragement of masturbation, either by self-stimulation or with a vibrator
- Kegel exercises for enhancing sexual response
- communication training and relationship enhancement for couples
- desensitization—learning to halt responses that are preventing orgasm, particularly in women with severe sexual anxiety

Drugs

Estrogen or a combination of estrogen and progesterone may be used to treat FOD in menopausal women and others with low hormone levels. FOD is sometimes treated with methyltestosterone, a synthetic form of the male sex hormone testosterone, although this practice is controversial and can have various side effects. Testosterone appears to be most effective for women with **low testosterone** levels resulting from surgical removal of the ovaries.

Alternatives

Zestra is a botanical massage oil that warms the clitoris and may increase sexual arousal and orgasm. L–arginine in various **nutritional supplements** relaxes blood vessels and increases blood flow to the genital area, especially the clitoris.

One of the most important factors in overcoming FOD is open and honest communication between partners about sexuality and sexual techniques. Erotic books or videos may help initiate such conversations. Sometimes focusing on clitoral stimulation is all that is needed to overcome FOD. Experimenting with different sexual positions may improve clitoral stimulation. Using a vibrator during sex can also help trigger orgasms.

Many women have found that Kegel exercises, which involve the repetitive contraction and relaxation of the pelvic floor muscles, can improve both the frequency and intensity of orgasmic experiences. Repeatedly stopping and starting a urine stream identifies the muscles to be exercised, working up to five sets of 10 contractions per day. The longer the contractions are held, the more benefit may result.

Prognosis

FOD can often be successfully treated with a combination of psychotherapy and guided sexual exercises. However women should not expect to always achieve orgasm in every situation; nor should they expect to always be satisfied with the strength and quality of their climax. Women whose FOD is not due to an identifiable condition or disorder may be more difficult to treat. Unresolved FOD usually results in a decline in sexual desire and can create resentment and conflict within relationships.

Prevention

Although there is no sure way to prevent FOD, reducing life factors that cause **stress** can be effective. Healthy attitudes toward sex and education about sexual stimulation and responses can help prevent FOD. Seeking counseling or psychotherapy for past trauma or relationship issues can help minimize FOD and other sexual dysfunction problems.

REVISED BY MARGARET ALIC, PhD

Female sexual arousal disorder

Definition

Female sexual arousal disorder (FSAD) is a woman's persistent or recurrent inability to achieve or maintain an adequate lubrication-swelling response during sexual activity. Sometimes FSAD is defined simply as the inability to become sexually aroused or to maintain arousal despite sexual desire. FSAD stems from both physiological and psychological factors. It often results in avoidance of sex, painful intercourse, and sexual tension in relationships.

Demographics

FSAD is common in older women due to decreased hormone production after **menopause** and medical conditions associated with **aging**. However, because FSAD often occurs in combination with other female sexual dysfunctions and can be difficult to distinguish from them, and because women are often reluctant to seek help for FSAD, it is difficult to determine its incidence. There is also disagreement within the medical community concerning the exact demarcations of the various female sexual dysfunctions. One published review of the medical literature found that 22–43% of women experience some form of **sexual dysfunction**. Another study found that about 20% of women have problems with sexual lubrication.

Description

FSAD results from a woman's inability to undergo lubrication and swelling in response to sexual desire and stimulation. This lack of response interferes with sexual desire and satisfying intercourse.

William Masters and Virginia Johnson—the first researchers to extensively examine the physical components of human sexuality—identified four stages of sexual response: excitement, plateau, climax or orgasm, and resolution. More recent models have included emotional aspects of arousal. One model identifies three stages: desire, arousal, and orgasm. FSAD affects the excitement or arousal stage.

The first physiological change in the female body upon becoming aroused or sexually excited is the expansion of the blood vessels in the pelvic region, allowing more blood to flow to the lower abdomen and genitals. Some women experience this as a feeling of fullness in the pelvis, and either consciously or involuntarily contract the muscles in the genital area. The increased blood flow normally results in transudation—the seepage of fluid through the walls of the blood vessels—in this case into the vagina to provide lubrication before and during intercourse. Vaginal lubrication can occur very rapidly, within one minute, and is often very noticeable. The increase in blood flow also expands the upper portion of the vagina, the uterus, and the cervix. The lower third of the vagina, the labia, and the area around the clitoris swell and may tingle. The breasts also swell slightly. Together these physiological changes constitute the lubrication-swelling response, designed to facilitate entry of the penis into the vagina.

With FSAD the lubrication-swelling response is either absent or is not maintained through the completion of sexual activity. The lack of arousal and lubrication can result in painful intercourse (**dyspareunia**), emotional distress, and/or relationship problems. FSAD can be lifelong or acquired and generalized or situation-specific.

Causes and symptoms

The major symptom of FSAD is insufficient transudation, often resulting in painful and unsatisfactory intercourse. In addition to vaginal dryness, there is a lack of swelling, tingling, or throbbing in the genital region. Generalized FSAD occurs with different partners and in many different situations, whereas situation-specific FSAD occurs only with certain partners or under particular circumstances. FSAD can be caused by psychological factors or a combination of psychological and physiological factors. Whereas some women have never had a normal lubrication-swelling response, others develop FSAD from physiological changes, such as illness or emotional **trauma**, or as a side effect of surgery, **radiation therapy** for cancer, or a medication. Physiologically based FSAD can lead to psychological problems that reinforce the disorder.

Arousal disorder that primarily affects the genitals can result from low estrogen or testosterone levels during and after menopause, as well as from vaginal or

ALFRED KINSEY (1894–1956)

Alfred Kinsey became a household name in the 1950s with his groundbreaking research on the sexual mores of American women and men. His two major texts, *Sexual Behavior in the Human Male* (1948) and *Sexual Behavior in the Human Female* (1953), opened the way for research into human sexuality.

Kinsey and his colleagues at the Institute for Sex Research at Indiana University conducted thousands of interviews with men and women about their sexual habits. The 804-page *Sexual Behavior in the Human Male* sold 185,000 copies in its first year and became a *New York Times* bestseller. The work was scientifically based and nonjudgmental, with frank descriptions of biological functions. Although early polls indicated that most Americans were relieved to have an honest and open airing of human sexual practices, there was a tremendous backlash from conservative and religious organizations. *Sexual Behavior in the Human Female* caused an even greater stir. Its more controversial findings included the low incidence of female frigidity, high rates of premarital and extramarital sex, the rapidness of erotic responses, and a detailed discussion of clitoral versus vaginal orgasm. As sales of the book reached 250,000 in the United States alone, Kinsey's methods and motives came under scrutiny. Evangelist Billy Graham stated: "It is impossible to estimate the damage this book will do to the already deteriorating morals of America." Kinsey's research funding was revoked and for the remainder of his life he struggled to find support for his work.

bladder infections, or changes in the skin around the vulva. Other physiological causes of FSAD include:

- insufficient sexual stimulation
- irritation from contraceptive creams or foams
- smoking, which decreases blood flow throughout the body
- illicit drug use
- lower levels of sex hormones due to breastfeeding
- medical conditions that cause changes in hormone levels, including thyroid disorders, adrenal gland disorders, or removal of the ovaries
- side effects of medications such as antidepressants, antipsychotics, sedatives, high-blood-pressure drugs, or birth control pills or other hormone-containing medications
- reduced blood flow due to damaged blood vessels in the pelvic region, often from medical conditions such as coronary artery disease, high blood pressure, or diabetes
- damage to nerves in the pelvic area, as from diabetes or multiple sclerosis

Psychological causes of FSAD include:

- fear or anxiety around sex
- chronic mild depression (dysthymia)
- emotional stress
- low self-esteem
- past sexual abuse
- emotional abuse
- bereavement
- self-image problems
- relationship problems
- other mental health disorders, including major depression, post-traumatic stress disorder, or obsessive-compulsive disorder

Diagnosis

Since most women occasionally experience difficulties with sexual arousal, a diagnosis of FSAD requires that the deficient lubrication-swelling response is persistent or has occurred intermittently over an extended period and causes emotional distress or relationship difficulties. The *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-5*) requires that FSAD be caused by psychological factors alone or a combination of psychological and physiological factors. Under these criteria, arousal disorder caused by physiological factors alone, such as injury, illness, or menopause is diagnosed as sexual dysfunction due to a general medical condition. Arousal disorder caused by medication or substance abuse alone is diagnosed as substance-induced sexual dysfunction. Arousal difficulties that are symptoms of a major psychological disorder, such as depression, or that result from inadequate sexual stimulation are not considered to be FSAD.

Examination

FSAD is usually diagnosed after a woman reports sexual difficulties to her gynecologist, family doctor, psychotherapist, or sex therapist. The physician will take complete medical, psychological, and sexual histories, including a list of medications and details about sexual symptoms. A **physical examination**, including a gynecological/pelvic exam, will be performed.

WWW.BOOKBAZ.IR

KEY TERMS

Clitoris—The small erectile organ at the front of the female vulva that is the site of female sexual pleasure.

Dyspareunia—Difficult or painful sexual intercourse.

Estrogen—Any of several naturally occurring or synthetic steroid hormones that promote the growth and maintenance of the female reproductive system.

Kegel exercises—Repetitive contractions to tone the pubococcygeal muscle of the pelvic floor for enhancing sexual response during intercourse or controlling incontinence.

Labia—The fatty folds of the vulva.

Testosterone—The primary male sex hormone, which is also produced at low levels in females.

Transudation—The passage of fluid, as through blood vessels into the vagina.

Vulva—The external female genital organs, including the labia majora, labia minora, clitoris, and vestibule of the vagina.

Tests

Blood and urine tests may be performed to rule out undiagnosed diabetes or other medical conditions. Hormone levels in the blood may be measured.

Treatment

FSAD treatment requires addressing underlying physiological and psychological causes. **Psychotherapy**, either individual or couples therapy, addresses emotions, communication, relationship problems, and problem-solving strategies. **Sex therapy** focuses primarily on the sexual dysfunction. However many couples experiencing sexual dysfunction develop relationship problems and can benefit from traditional psychotherapy even after sexual arousal difficulties are resolved.

The U.S. Food and Drug Administration (FDA) has approved one medical device for treating FSAD. The Eros-Clinical Therapy Device (Eros-CTD) is a small vacuum pump that fits over the clitoral area and exerts a gentle sucking action that stimulates blood flow. In clinical trials the device has proved safe and effective for increasing blood flow, sensation, and vaginal lubrication.

Drugs

Sometimes medications, such as the type or timing of an antidepressant, can be adjusted. Poor lubrication related to decreasing hormone levels associated with menopause can often be successfully treated with **hormone replacement therapy** (HRT), such as estrogen or testosterone. Nonprescription lubricating gels and hormone creams can supplement a woman's natural lubricant. These are especially useful for pre- and postmenopausal women and for those with occasional arousal difficulties.

Research is focusing on new drugs that increase blood flow to the female genitals, thereby improving lubrication. Some of these drugs are aimed at increasing nitric oxide levels, similar to the drug sildenafil (Viagra) for men.

Alternatives

A type of **meditation** called mindfulness, which promotes increased awareness and acceptance, has been found to be helpful in treating FSAD, at least when practiced in the context of **group therapy**.

Home remedies for FSAD include:

- Kegel exercises that increase blood flow to the vulvar and vaginal tissues
- relaxation techniques
- aerobic exercise
- changing the circumstances and settings of sexual activity
- sexual activities other than vaginal intercourse
- exploring sexual techniques that increase stimulation
- experimenting with a vibrator, fantasies, or erotic movies
- couples focusing exercises to enhance intimacy, lessen anxiety, and increase arousal

Prognosis

Because of the multiple causes of FSAD individual responses to treatment vary widely. Poor lubrication related to menopause generally has a favorable prognosis. Stress-related causes of FSAD can often be resolved. However couples may need to work through relationship issues that have caused FSAD—or resulted from it—before sexual arousal improves. This process takes time and a joint commitment to problem solving.

Prevention

A healthy, well-balanced diet, adequate rest, regular gynecological exams, and seeking counseling or psychotherapy for problems can minimize the risk for sexual arousal disorder. Aerobic **exercise** and not **smoking** also can help prevent FSAD.

Fetal alcohol syndrome

Definition

Fetal alcohol syndrome (FAS) is a pattern of **birth defects**, learning, and behavioral problems affecting individuals whose mothers drank alcohol during **pregnancy**.

Demographics

The occurrence FAS/FASD is independent of race, ethnicity, or gender of the individual. Individuals from different genetic backgrounds exposed to similar amounts of alcohol during pregnancy may show different symptoms of FAS. The reported rates of FAS vary widely among different populations studied depending on the degree of alcohol use within the population and the monitoring methods used. Studies by the Centers for Disease Control (CDC) show that FAS occurs in 0.5 to 2 per 1,000 live births in different areas of the United States. FASDs are believed to occur approximately three times as often as FAS.

Description

FAS is the most severe of a range of disorders represented by the term fetal alcohol spectrum disorder (FASD). FAS/FASD is caused by exposure of a developing fetus to alcohol. FASD is used to describe individuals with some, but not all, of the features of FAS. Other terms used to describe specific types of FASD are alcohol-related neurodevelopmental disorder (ARND) and alcohol-related birth defects (ARBD).

WWW.BOOKBAZ.IR

FAS is the most common preventable cause of intellectual disabilities (ID). This condition was first recognized and reported in the medical literature in 1968 in France and in 1973 in the United States. Alcohol is a teratogen, the term used for any drug, chemical, maternal disease, or other environmental exposure that can cause birth defects or functional impairment in a developing fetus. Some features of FAS that may be present at birth include low birthweight, **prematurity**, and microcephaly. Characteristic facial features may be present at birth or may become more obvious over time. Signs of brain damage include delays in development, behavioral abnormalities, and ID, but affected individuals exhibit a wide range of abilities and disabilities.

FAS is a lifelong condition. It is not curable and has serious long-term consequences. Learning, behavioral, and emotional problems are common in adolescents and adults with FAS/FASD. The costs of FAS to the American economy were estimated in 2006 as $321 million annually.

Risk factors

The only risk factor for a child to develop FAS is the consumption of alcohol by a woman who is pregnant. There is no known amount of alcohol use that is safe during pregnancy, nor is there a particular stage of pregnancy during which alcohol use is safe.

Causes and symptoms

The only cause of FAS is maternal use of alcohol during pregnancy. FAS is not a genetic or inherited disorder. Alcohol consumed by the mother freely crosses the placenta and damages the developing fetus. Alcohol use by the father cannot cause FAS. Not all offspring who are exposed to alcohol during pregnancy have signs or symptoms of FAS; individuals of different genetic backgrounds may be more or less susceptible to the damage that alcohol can cause. The amount of alcohol, stage of development of the fetus, and the pattern of alcohol use create the range of symptoms that encompass FASD.

Classic features of FAS include short stature, low birthweight, poor weight gain, microcephaly, and a characteristic pattern of abnormal facial features. These facial features in infants and children may include small eye openings (measured from inner corner to outer corner), epicanthal folds (folds of tissue at the inner corner of the eye), small or short nose, low or flat nasal bridge, smooth or poorly developed philtrum (the area of the upper lip above the colored part of the lip and below the nose), thin upper lip, and small chin. Some of these features are nonspecific, meaning they can occur in other conditions, or be appropriate for age, racial, or family background.

Other major and minor birth defects that have been reported to occur in conjunction with FAS/FASD include **cleft palate**, congenital heart defects, **strabismus**, **hearing loss**, defects of the spine and joints, alteration of the hand creases, small fingernails, and toenails. Since FAS was first described in infants and children, the diagnosis is sometimes more difficult to recognize in older adolescents and adults. Short stature and microcephaly remain common features, but weight may normalize, and the individual may actually become overweight for his/her height. The chin and nose grow proportionately more than the middle part of the face, and dental crowding may become a problem. The small eye openings and the appearance of the upper lip and philtrum may continue to be characteristic. Pubertal changes typically occur at the normal time.

Newborns with FAS may have difficulty nursing due to a poor sucking response, have irregular sleep-wake cycles, decreased or increased muscle tone, seizures or **tremors**. Delays in achieving developmental milestones such as rolling over, crawling, walking, and talking may become apparent in infancy. Behavior and learning difficulties typical in the preschool or early school years include poor attention span, hyperactivity, poor motor skills, and slow language development. Attention deficit-hyperactivity disorder (**ADHD**) is often associated with FASD. Learning disabilities or ID may be diagnosed during this time.

During middle school and high school years the behavioral difficulties and learning difficulties can be significant. Memory problems, poor judgment, difficulties with daily living skills, difficulties with abstract reasoning skills, and poor social skills are often apparent by this time. It is important to note that animal and human studies have shown that neurologic and behavioral abnormalities can be present without characteristic facial features. These individuals may not be identified as having FAS, but may fulfill criteria for alcohol-related neurodevelopmental disorder (ARND).

FASD continues to affect individuals into adulthood. One study looked at FAS adults and found that about 95% had mental health problems, 82% lacked the ability to live independently, 70% had problems staying employed, 60% had been in trouble with the law, and 50% of men and 70% of women were alcohol or drug abusers.

KEY TERMS

Cleft plate—A congenital malformation in which there is an abnormal opening in the roof of the mouth that allows the nasal passages and the mouth to be improperly connected.

IQ—Abbreviation for Intelligence Quotient. Compares an individual's mental age to his/her true or chronological age and multiplies that ratio by 100.

Microcephaly—An abnormally small head.

Miscarriage—Spontaneous pregnancy loss.

Placenta—The organ responsible for oxygen and nutrition exchange between a pregnant mother and her developing baby.

Strabismus—An improper muscle balance of the ocular muscles resulting in crossed or divergent eyes.

Teratogen—Any drug, chemical, maternal disease, or exposure that can cause physical or functional defects in an exposed embryo or fetus.

Another long-term study found that the average IQ of the group of adolescents and adults with FAS in the study was 68 (70 is lower limit of the normal range). However, the range of IQ was quite large, ranging from a low of 20 (severely intellectually disabled) to a high of 105 (normal). Academic abilities and social skills were also below normal levels. The average achievement levels for reading, spelling, and arithmetic were fourth grade, third grade, and second grade, respectively. The Vineland Adaptive Behavior Scale was used to measure adaptive functioning in these individuals. The composite score for this group showed functioning at the level of a seven-year-old. Daily living skills were at a level of nine years, and social skills were at the level of a six-year-old.

Diagnosis

In 1996, the Institute of Medicine suggested a five-level system to describe the birth defects, learning problems, and behavioral difficulties in offspring of women who drank alcohol during pregnancy. This system contains criteria including confirmation of maternal alcohol exposure, characteristic facial features, growth problems, learning and behavioral problems, and birth defects known to be associated with prenatal alcohol exposure.

FAS is a clinical diagnosis, which means that no blood, x-ray, or psychological test can be performed to confirm the suspected diagnosis. The diagnosis is made based on the history of maternal alcohol use, and detailed **physical examination** for the characteristic major and minor birth defects and characteristic facial features. It is often helpful to examine siblings and parents of an individual suspected of having FAS, either in person or by photographs, to determine whether findings on the examination might be familial, of if other siblings may also be affected. Sometimes, genetic tests are performed to rule out other conditions that may present with developmental delay or birth defects. Individuals with developmental delay, birth defects, or other unusual features are often referred to a clinical geneticist, developmental pediatrician, or neurologist for evaluation and diagnosis of FAS. Psychoeducational testing to determine IQ and/or the presence of learning disabilities may also be part of the evaluation process.

Treatment

There is no cure for FAS. The disorder is irreversible. Nothing can change the physical features or brain damage associated with maternal alcohol use during the pregnancy. Children should have psychoeducational evaluation to help plan appropriate educational interventions. Common associated diagnoses such ADHD, depression, or **anxiety** can be recognized and treated. The disabilities that present during childhood persist into adult life. However, some of the behavioral problems mentioned may be avoided or lessened by early and correct diagnosis, better understanding of the life-long complications of FAS, and intervention. The goal of treatment is to help the individual affected by FAS become as independent and successful in school, employment, and social relationships as possible.

Prognosis

The prognosis for FAS/FASD depends on the severity of birth defects and the brain damage present at birth. **Miscarriage**, **stillbirth**, or death in the first few weeks of life may be outcomes in very severe cases. Generally individuals with FAS have a long list of mental health problems and associated social difficulties: alcohol and drug problems, inappropriate sexual behavior, problems with employment, trouble with the law, inability to live independently, and often confinement in prison, drug or alcohol treatment centers, or psychiatric institutions.

Some of the factors that have been found to reduce the risk of learning and behavioral disabilities in FAS individuals include diagnosis before the age of

WWW.BOOKBAZ.IR

six years, stable and nurturing home environments, never having experienced personal violence, and referral and eligibility for disability services. Some physical birth defects associated with FAS are treatable with surgery. The long-term data help in understanding the difficulties that individuals with FAS encounter throughout their lifetime and can help families, caregivers, and professionals provide the care, supervision, education and treatment geared toward their special needs.

Prevention

FAS and FASD are completely preventable by avoiding all use of alcohol while pregnant. Prevention efforts include public education efforts aimed at the entire population, not just women of child bearing age, appropriate treatment for women with high-risk drinking habits, and increased recognition and knowledge about FAS/FASD by professionals, parents, and caregivers.

Fetal death *see* **Stillbirth**

Fetal hemoglobin test

Definition

Fetal hemoglobin (Hemoglobin F), alkali-resistant hemoglobin, HBF (or Hb F), is the major hemoglobin component in the bloodstream of the fetus. After birth, it decreases rapidly until only traces are found in normal children and adults.

Purpose

The determination of fetal hemoglobin is an aid in evaluating low concentrations of hemoglobin in the blood (anemia), as well as the hereditary persistence of fetal hemoglobin, and a group of inherited disorders affecting hemoglobin, among which are the thalassemias and sickle cell anemia.

Description

At birth, the newborn's blood is comprised of 60–90% of fetal hemoglobin. The fetal hemoglobin then rapidly decreases to 2% or less after the second to

fourth years. By the time of adulthood, only traces (0.5% or less) are found in the bloodstream.

In some diseases associated with abnormal hemoglobin production (see section on Hemoglobinopathy), fetal hemoglobin may persist in larger amounts. When this occurs, the elevation raises the question of possible underlying disease.

For example, HBF can be found in higher levels in hereditary hemolytic **anemias**, in all types of leukemias, in **pregnancy**, diabetes, thyroid disease, and during anticonvulsant drug therapy. It may also reappear in adults when the bone marrow is overactive, as in the disorders of **pernicious anemia**, **multiple myeloma**, and metastatic cancer in the marrow. When HBF is increased after age four, it should be investigated for cause.

Hemoglobinopathy

Hemoglobin is the oxygen-carrying pigment found in red blood cells. It is a large molecule made in the bone marrow from two components, heme and globin.

Defects in hemoglobin production may be either genetic or acquired. The genetic defects are further subdivided into errors of heme production (porphyria), and those of globin production (known collectively as the **hemoglobinopathies**).

Hemoglobinopathy is divided into two categories. In the first category, abnormal globin chains give rise to abnormal hemoglobin molecules. In the second category, normal hemoglobin chains are produced but in abnormal amounts. An example of the first category is the disorder of sickle cell anemia, the inherited condition characterized by curved (sickle-shaped) red blood cells and chronic **hemolytic anemia**. Disorders in the second category are called the thalassemias, which are further divided into types according to which amino acid chain is affected (alpha or beta), and whether there is one defective gene (**thalassemia** minor) or two defective genes (thalassemia major).

Preparation

This test requires a blood sample. The patient is not required to be in a **fasting** state (nothing to eat or drink for a period of hours before the test).

Risks

Risks for this test are minimal, but may include slight bleeding from the blood-drawing site, **fainting** or feeling lightheaded after venipuncture, or hematoma (blood accumulating under the puncture site).

KEY TERMS

Anemia—A disorder characterized by a reduced blood level of hemoglobin, the oxygen-carrying pigment of blood.

Hemolytic anemia—A form of anemia caused by premature destruction of red cells in the bloodstream (a process called hemolysis). Hemolytic anemias are classified according to whether the cause of the problem is inside the red blood cell (in which case it is usually an inherited condition), or outside the cell (usually acquired later in life).

Results

Reference values vary from laboratory to laboratory but are generally found within the following ranges:

- six months to adult: up to 2% of the total hemoglobin
- newborn to six months: up to 75% of the total hemoglobin

Abnormal results

Greater than 2% of total hemoglobin is abnormal.

Fetal surgery

Definition

Fetal surgery is a surgical procedure performed on a fetus prior to birth.

Purpose

In most cases fetal surgery is performed only when the fetus is not expected to survive delivery or live long after birth without prenatal intervention. The most

WWW.BOOKBAZ.IR

common fetal surgeries are for conditions in which the newborn will not be able to breathe on its own.

Most fetal surgeries are performed for:

- Urinary tract obstructions in males, usually caused by a narrowing of the urinary tract, in which urine backs up and injures the kidneys.
- Congenital diaphragmatic hernia (CDH), a condition in which the diaphragm—the muscle that separates the chest and the abdomen—does not form completely.
- Congenital cystic adenomatoid malformation (CCAM), a condition in which one or more lobes of the lungs become fluid-filled sacs called cysts. Large CCAMs may prevent lung development, cause heart failure, or prevent the fetus from ingesting amniotic fluid.
- Sacrococcygeal teratoma (SCT), tumors at the base of the tailbone. The most common tumor in newborns, occurring in one out of every 35,000–40,000 births, some prenatal SCTs are very large, hard, and full of blood vessels, and can stress the heart.
- Twin-to-twin transfusion syndrome (TTTS), a condition in which, because of abnormal blood-vessel connections in the placenta, one twin pumps the circulating blood for both twins. Affecting up to 15% of twins sharing a placenta (monochorionic), TTTS can lead to a variety of problems including heart failure. Procedures to treat this condition are the most commonly performed type of fetal surgery.
- Twin reversed arterial perfusion (TRAP) sequence, a condition in which one twin lacks a heart. Occurring in about 1% of monochorionic twins, the healthy twin pumps all of the blood and, if untreated, 50–75% of these normal twins die.

Other conditions that may be treated by fetal surgery include:

- various congenital defects that block air passages and will prevent the newborn from breathing on its own
- various lung malformations
- omphalocele, a birth defect in which portions of the stomach, liver, and intestines protrude through an opening in the abdominal wall
- fetal gastroschisis—a birth defect in which the stomach and intestines protrude through improperly formed abdominal wall muscles and float in the amniotic fluid
- bowel obstructions, usually caused by a narrowing in the small intestine
- hypoplastic left heart syndrome, in which the blood flow through the left side of the heart is obstructed
- X-linked severe combined immunodeficiency syndrome
- spina bifida (myelomeningocele)—the second most common birth defect in the United States, affecting one out of every 2,000 newborns. It is a lesion or hole where the nerves of the spinal cord are not completely enclosed and is not considered to be life-threatening.

Precautions

Fetal surgery involves:

- serious risks for the mother and fetus
- travel to a hospital that performs the procedure
- possibly having to stay near the hospital until delivery
- extended postoperative bed rest, sometimes until delivery
- a significant financial commitment

Considerably more research is needed to ascertain whether the risks associated with **prenatal surgery** (infection, fluid loss, and significant **prematurity**) outweigh the risks associated with awaiting birth in order to address the particular defect.

Description

Fetal surgery may be referred to as prenatal surgery, antenatal surgery, or maternal-fetal surgery. There are only about 600 candidates for fetal surgery in the United States each year. Of these, only about 10% actually undergo the procedure. Most fetal surgeries are performed between 18 and 26 weeks of gestation. Some surgeries may not be covered by insurance.

Fetal surgery usually requires a general anesthetic, although sometimes an epidural anesthetic to numb the abdominal region may be used. The fetus receives the anesthetic via the mother's blood. An anesthesiologist and a perinatologist monitor the heart rates of the mother and fetus during the procedure.

Fetal surgeries include:

- inserting a device into the fetal bladder to drain urine into the amniotic sac for treating urinary tract obstruction
- draining or removing CCAMs
- destroying blood vessels leading to a large SCT
- amnioreduction for TTTS, in which a syringe through the mother's abdomen is used to remove fluid from

the overfilled amniotic sac and replace it in the depleted sac of the twin pumping the blood

- destroying abnormal blood vessel connections in the placenta of TTTS twins (this is the most frequently performed type of fetal surgery)
- severing the connections between TRAP sequence twins
- experimental hematopoietic-stem-cell transplants for X-linked severe combined immunodeficiency syndrome
- closing the lesion in spina bifida

Open surgeries

In open fetal surgeries incisions are made through the mother's abdominal wall and the fetus is partially removed from the uterus or the entire uterus is removed through the mother's abdomen. Using **ultrasound** as a guide, the surgeon feels for the affected fetal part. The surgeon may knead and push on the uterus to move or flip the fetus away from the placenta, the disk-shaped organ within the uterus that supplies the fetal blood. A narrow tube is placed through a tiny hole in the uterine wall to drain and collect the amniotic fluid. Opening the uterus is the riskiest part of fetal surgery. The first incision is made at a point away from the placenta to prevent damaging it. Following the procedure the fetus is replaced in the uterus and the incision is stitched. Prior to the final stitch the amniotic fluid is re-injected into the uterus. The uterus is repositioned in the mother's body cavity and her abdominal wall is closed.

The first successful open fetal surgery was performed in 1981 for a urinary tract obstruction. The first successful open fetal surgery for CDH was performed in 1989.

Fetal open surgery for CCAM requires opening the fetus's chest. If a large cyst does not have a hard component, procedures called thoracoamniotic shunting or catheter decompression may be used to drain it. Otherwise the surgeon must remove part or all of the cyst. The first successful resection (removal) of a CCAM from a fetal lung was performed in 1990. The first resectioning of a fetal SCT was performed in 1992.

In fetal surgery for **spina bifida**, an incision the size of a small fist is made in the uterus. The surgeon loosens and lifts the tissues of the spinal-canal lesion and stitches them closed. Between 1997 and 2004, more than 200 open surgeries were performed for spina bifida. The surgery was available only as part of a prospective randomized clinical trial.

Less invasive procedures

For urinary tract obstructions, a needle may be used to insert a catheter through the mother's abdomen and uterus and into the fetal bladder where it drains the urine into the amniotic fluid. The catheter may have a wire mesh that expands in the bladder to prevent it from plugging up or dislodging.

The first successful fetoscopic temporary tracheal occlusion for CDH was performed in 1996. Small openings are made in the uterus and a tiny fiber-optic fetoscope is inserted to guide the operation. A needle-like instrument is used to place a balloon in the fetus's trachea to prevent lung fluid from escaping through the mouth, enabling the lungs to expand, grow, and push the abdominal organs out of the chest. The balloon is removed at birth.

Hypoplastic left heart syndrome is treated by passing a needle, guided by ultrasound, through the mother's abdominal wall, into the uterus, and into the fetal heart. A catheter is passed through the needle across the fetus's aortic valve. A balloon is inflated, opening the valve and allowing blood to flow through the left side of the heart.

RADIOFREQUENCY ABLATION. Radiofrequency ablation (RFA) sometimes is used for SCT. Guided by ultrasound, a needle is inserted through the mother's abdomen and uterus and into the tumor. Radiofrequency waves sent through the needle destroy the blood supply to the tumor with heat. This slows the tumor's growth and may enable the fetus to survive until delivery. The first RFA of an SCT was performed in 1998.

TRAP sequence also may be treated by RFA. A 3-mm needle targets the exact point where the blood enters the twin without a heart. Using an echocardiographic device, RFA is applied until the blood vessels and surrounding tissue are destroyed and the blood flow is halted. This procedure has eliminated the need for open surgery to treat TRAP sequence.

LASER TREATMENT. If TTTS does not respond to amnioreduction, laser treatment to halt the abnormal blood circulation may be attempted. A thin fetoscope is inserted through the mother's abdominal and uterine walls and into the amniotic cavity of the recipient twin to examine the surface placental blood vessels. The abnormal blood vessel connections are located and eliminated with a laser beam. The first successful fetoscopic laser treatment for TTTS was performed in 1999.

WWW.BOOKBAZ.IR

EXIT. Ex utero intrapartum treatment (EXIT) is a surgery performed for a congenital defect that blocks a fetal airway. The fetus is removed from the womb by **cesarean section** but the umbilical cord is left intact so that the mother's placenta continues to sustain the fetus. After the air passage is cleared, the umbilical cord is cut and the newborn can breathe on its own. The EXIT procedure is used for various types of airway obstruction including CCAM.

Preparation

The decision to perform fetal surgery is made on the basis of detailed ultrasound imaging of the fetus—including echocardiograms that use ultrasound to obtain images of the heart—as well as other diagnostic tools. Consultations include a perinatologist, a neonatologist, a pediatric surgeon, a clinical nurse specialist, and a social worker. Since additional congenital defects preclude fetal surgery, **amniocentesis** or chorionic villi sampling (CVS) are used to check for chromosomal abnormalities in the fetus.

Prior to surgery the mother must:

- arrange for postoperative bed rest to prevent preterm labor
- prepare for the possibility of remaining near the hospital until delivery
- receive betamethasone, a steroid, in two intramuscular injections 12–24 hours apart to accelerate fetal lung maturation
- wear a fetal/uterine monitor

The mother usually receives medications called tocolytics to prevent contractions and labor during and after surgery. These include:

- terbutalin
- indocin suppositories before surgery and up to 48 hours after surgery
- magnesium sulfate for one to two days after surgery with careful monitoring
- nifedipine every four to six hours as the indocin is decreased, continuing until 37 weeks of gestation or delivery

Aftercare

In addition to usual postsurgical care, the mother:

- usually remains in the hospital for four to seven days
- lies on her side to help prevent contractions and ensure the best possible fetal circulation
- has a transparent dressing over the abdominal incision for fetal monitoring
- has continuous electronic fetal/uterine monitoring to check the fetal heart, the uterine response to tocolytics, and to watch for signs of preterm labor

After **discharge from the hospital** the mother is on modified bed rest, lying on her side, until 37 weeks of gestation. This increases blood flow to the fetus and reduces pressure on the cervix to help prevent uterine contractions. She sees a perinatologist once a week and has at least one ultrasound per week.

Risks

Most fetal surgeries are high risk and may be considered experimental. The greatest risk is that the placenta will be nicked during surgery, causing blood hemorrhaging, uterine contractions, and birth of a premature infant who may not survive. Preterm labor is the most common complication of fetal surgery. Low amniotic fluid is another complications, which itself can lead to **birth defects** and lung problems after birth. Fetoscopic surgeries are less dangerous and traumatic than open fetal surgery and reduce the risk of **premature labor**. Subsequent children of a mother who has undergone fetal surgery usually are delivered by cesarean section because of uterine scarring.

Maternal risks

Risks to the mother include:

- extensive blood loss
- complications from general anesthesia
- side effects—potentially fatal—from medications to control premature labor
- rupture of the uterine incision
- infection of the wound or uterus
- psychological stress
- inability to have additional children
- death

Fetal risks

All fetuses that undergo surgery are born prematurely. Those born even six weeks early are at risk for walking and talking delays and learning disabilities. Infants born at 30 weeks of gestation or less are at risk for blindness, **cerebral palsy**, and brain hemorrhages.

About 25% of women undergoing fetal surgery lose some amniotic fluid, often because of leakage at the uterine incision. Amniotic fluid is essential for lung development and protects the fetus from injury and infection. If all of the amniotic fluid is lost, the fetal lungs may not develop properly. Without the fluid

KEY TERMS

Amniocentesis—Withdrawal of amniotic fluid through the mother's abdominal wall, using a needle and syringe, to test for fetal disorders.

Amniotic fluid—The watery fluid within the amniotic sac that surrounds the fetus.

Cesarean section—C-section; incision through the abdominal and uterine walls to deliver a baby.

Chorion—The outermost membrane of the sac enclosing the fetus.

Chorionic villus sampling (CVS)—The removal of fetal cells from the chorion for the diagnosis of genetic disorders.

Congenital cystic adenomatoid malformation (CCAM)—A condition in which one or more lobes of the fetal lungs develop into fluid-filled sacs called cysts.

Congenital diaphragmatic hernia (CDH)—A condition in which the fetal diaphragm—the muscle dividing the chest and abdominal cavity—does not close completely.

Echocardiography—Ultrasonic examination of the heart.

Ex utero intrapartum treatment (EXIT)—A cesarean section in which the infant is removed from the uterus but the umbilical cord is not cut until after surgery; treats congenital defects that block an air passage.

Fetoscope—A fiber-optic instrument for viewing the fetus inside the uterus.

Monochorionic twins—Twins that share a single placenta.

Omphalocele—A congenital hernia in which a small portion of the fetal abdominal contents, covered by a membrane sac, protrudes into the base of the umbilical cord.

Placenta—The organ within the uterus that provides nourishment to the fetus.

Radiofrequency ablation (RFA)—A procedure in which radiofrequency waves are used to destroy blood vessels and tissues.

Sacrococcygeal teratoma (SCT)—A tumor occurring at the base of the fetus's tailbone.

Spina bifida—Myelomeningocele; a congenital defect in which the fetal backbone and spinal canal do not close completely, allowing the spinal cord and its surrounding membranes to protrude.

Tocolytic—A medication that inhibits uterine contractions.

Twin reversed arterial perfusion (TRAP) sequence—A condition in which one fetus lacks a heart and the other fetus pumps the blood for both.

Twin-to-twin transfusion syndrome (TTTS)—A condition in monochorionic twins in which there is a connection between the two circulatory systems so that the donor twin pumps the blood to the recipient twin without a return of blood to the donor.

Ultrasound—A procedure that uses high-frequency sound waves to image a fetus.

cushion in which the fetus floats, the umbilical cord may be compressed, causing death.

Other risks to the fetus include:

- birth during surgery
- separation of the tissues surrounding the amniotic fluid sac and the uterus, causing early delivery or interference with blood flow to some fetal body part such as an arm or leg
- intrauterine infection requiring immediate birth of the fetus
- further damage to the spinal cord and nerves during surgery to treat spina bifida
- brain damage
- physical deformities
- death

Results

Although fetal surgeries heal without scarring, it is difficult to predict their outcome because relatively few have been performed. Results for specific conditions include:

- Fetal surgery for CDH lessens the severity of the condition so that the fetus usually survives delivery and lives long enough to undergo corrective surgery.
- Thoracoamniotic shunting for CCAM usually results in infant survival.
- The infant survival rate following prenatal removal of solid CCAMs is about 50%.
- RFA to slow the growth of a tumor usually enables the fetus to survive delivery, after which the tumor can be removed.

WWW.BOOKBAZ.IR

- The infant survival rate following prenatal treatment for TTTS is about 90% for both twins and 70% for one twin. Since TTTS is a progressive disorder, early intervention may prevent later complications.

Spina bifida arises during the first month of fetal development. Fluid leaking from the spinal cord and exposure of the cord to amniotic fluid causes damage throughout gestation. Lesions higher up in the spinal cord can cause severe deformities, **paralysis**, and mental retardation. Fetal surgery may reduce the abnormalities, although it does not cure the condition. Babies who survive fetal surgery appear to be 33 to 50% less likely to have **hydrocephalus**, a condition that requires surgically implanted tubes or shunts to remove fluid from the ventricles (cavities) of the brain. The surgery also appears to reverse hindbrain herniation, in which the back of the brain slips down into the spinal canal, causing breathing and swallowing problems and death in 15% of affected children. Children who had fetal surgery to treat spina bifida appear to have better brain function than those who did not. However fetal surgery does not prevent two of the most serious conditions associated with spina bifida: leg movement and bladder and bowel control. The long-term prognosis for these children is not known.

Margaret Alic, PhD

Fever

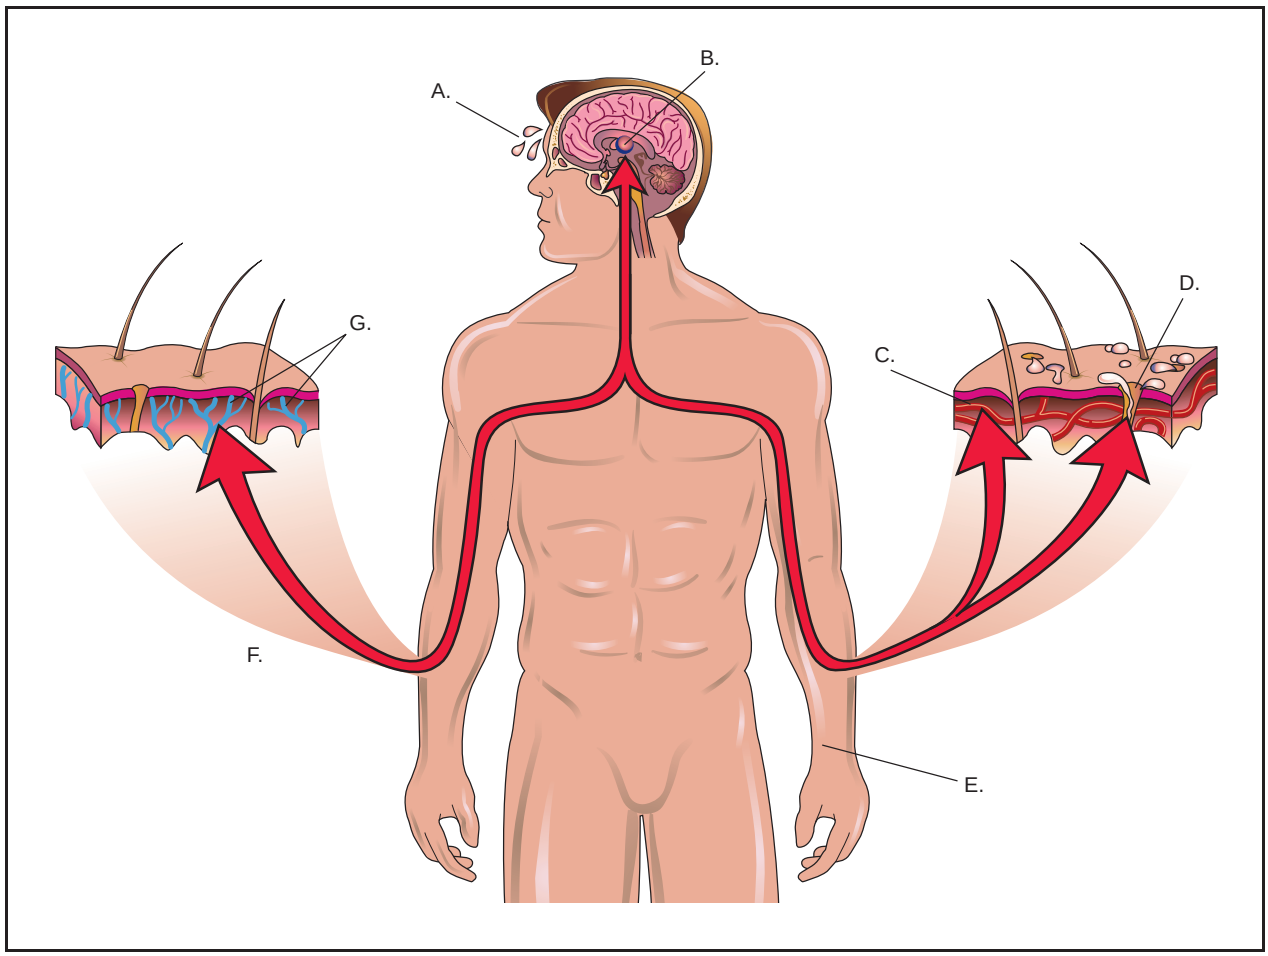
Definition

A fever is any body temperature elevation over 100°F (37.8°C).

Description

A healthy person's body temperature fluctuates between 97°F (36.1°C) and 100°F (37.8°C), with the average being 98.6°F (37°C). The body maintains stability within this range by balancing the heat produced by the metabolism with the heat lost to the environment. The "thermostat" that controls this process is located in the hypothalamus, a small structure located deep within the brain. The nervous system constantly relays information about the body's temperature to the thermostat, which in turn activates different physical responses designed to cool or warm the body, depending on the circumstances. These responses include: decreasing or increasing the flow of blood from the body's core, where it is warmed, to the surface, where it is cooled; slowing down or speeding up the rate at which the body turns food into energy (metabolic rate); inducing shivering, which generates heat through muscle contraction; and inducing sweating, which cools the body through evaporation.

A fever occurs when the thermostat resets at a higher temperature, primarily in response to an infection. To reach the higher temperature, the body moves blood to the warmer interior, increases the metabolic rate, and induces shivering. The "chills" that often accompany a fever are caused by the movement of blood to the body's core, leaving the surface and extremities cold. Once the higher temperature is achieved, the shivering and chills stop. When the infection has been overcome or drugs such as **aspirin** or **acetaminophen** (Tylenol) have been taken, the thermostat resets to normal and the body's cooling mechanisms switch on: the blood moves to the surface and sweating occurs.



A dramatic rise in body temperature often includes the following symptoms: A. Loss of fluid results in dehydration. B. The hypothalamic set-point is increased, raising metabolism. C. Blood vessels in skin dilate. D. Sweat glands produce excess perspiration. E. Increased pulse rate. F. Increased hypothalmic set-point may introduce chills and shivering to promote heat production from muscles. G. Skin becomes more heat-sensitive. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Fever is an important component of the immune response, though its role is not completely understood. Physicians believe that an elevated body temperature has several effects. The immune system chemicals that react with the fever-inducing agent and trigger the resetting of the thermostat also increase the production of cells that fight off the invading bacteria or viruses. Higher temperatures also inhibit the growth of some bacteria, while at the same time speeding up the chemical reactions that help the body's cells repair themselves. In addition, the increased heart rate that may accompany the changes in blood circulation also speeds the arrival of white blood cells to the sites of infection.

Causes and symptoms

Fevers are primarily caused by viral or bacterial infections, such as **pneumonia** or **influenza**. However, other conditions can induce a fever, including allergic reactions; autoimmune diseases; **trauma**, such as breaking a bone; cancer; excessive exposure to the sun; intense **exercise**; hormonal imbalances; certain drugs; and damage to the hypothalamus. When an infection occurs, fever-inducing agents called pyrogens are released, either by the body's immune system or by the invading cells themselves, that trigger the resetting of the thermostat. In other circumstances, the immune system may overreact (allergic reactions) or become damaged (autoimmune diseases), causing the uncontrolled release of pyrogens. A **stroke** or tumor can damage the hypothalamus, causing the body's thermostat to malfunction. Excessive exposure to the sun or intensely exercising in hot weather can result in heat stroke, a condition in which the body's cooling mechanisms fail. **Malignant hyperthermia** is a rare,

WWW.BOOKBAZ.IR

KEY TERMS

Antipyretic—A drug that lowers fever, like aspirin or acetaminophen.

Autoimmune disease—Condition in which a person's immune system attacks the body's own cells, causing tissue destruction.

Febrile seizure—Convulsions brought on by fever.

Malignant hyperthermia—A rare, inherited condition in which a person develops a very high fever when given certain anesthetics or muscle relaxants in preparation for surgery.

Meningitis—A potentially fatal inflammation of the thin membrane covering the brain and spinal cord.

Metabolism—The chemical process by which the body turns food into energy, which can be given off as heat.

Pyrogen—A chemical circulating in the blood that causes a rise in body temperature.

Reye's syndrome—A disorder principally affecting the liver and brain, marked by the rapid development of life-threatening neurological symptoms.

inherited condition in which a person develops a very high fever when given certain anesthetics or **muscle relaxants** in preparation for surgery.

How long a fever lasts and how high it may go depends on several factors, including its cause, the age of the patient, and his or her overall health. Most fevers caused by infections are acute, appearing suddenly and then dissipating as the immune system defeats the infectious agent. An infectious fever may also rise and fall throughout the day, reaching its peek in the late afternoon or early evening. A low-grade fever that lasts for several weeks is associated with autoimmune diseases such as lupus or with some cancers, particularly leukemia and lymphoma.

Diagnosis

A fever is usually diagnosed using a thermometer. A variety of different thermometers are available, including traditional glass and mercury ones used for oral or rectal temperature readings and more sophisticated electronic ones that can be inserted in the ear to quickly register the body's temperature. For adults and older children, temperature readings are usually taken orally. Younger children who cannot or will not hold a thermometer in their mouths can have their temperature taken by placing an oral thermometer under their armpit. Infants generally have their temperature taken rectally using a rectal thermometer.

As important as registering a patient's temperature is determining the underlying cause of the fever. The presence or absence of accompanying symptoms, a patient's medical history, and information about what he or she may have ingested, any recent trips taken, or possible exposures to illness help the physician make a diagnosis. Blood tests can aid in identifying an infectious agent by detecting the presence of antibodies against it or providing samples for growth of the organism in a culture. Blood tests can also provide the doctor with white blood cell counts. **Ultrasound** tests, **magnetic resonance imaging** (MRI) tests, or computed tomography (CT) scans may be ordered if the doctor cannot readily determine the cause of a fever.

Treatment

Physicians agree that the most effective treatment for a fever is to address its underlying cause, such as through the administration of **antibiotics**. Also, because a fever helps the immune system fight infection, it usually should be allowed to run its course. Drugs to lower fever (antipyretics) can be given if a patient (particularly a child) is uncomfortable. These include aspirin, acetaminophen (Tylenol), and ibuprofin (Advil). Aspirin, however, should not be given to a child or adolescent with a fever since this drug has been linked to an increased risk of Reye's syndrome. Bathing a patient in cool water can also help alleviate a high fever.

A fever requires emergency treatment under the following circumstances:

- newborn (three months or younger) with a fever higher than 100.5°F (38°C)
- infant or child with a fever higher than 103°F (39.4°C)
- fever accompanied by severe headache, neck stiffness, mental confusion, or severe swelling of the throat

A very high fever in a small child can trigger seizures (febrile seizures) and therefore should be treated immediately. A fever accompanied by the listed symptoms can indicate the presence of a serious infection, such as **meningitis**, and should be brought to the immediate attention of a physician.

Prognosis

Most fevers caused by infection end as soon as the immune system rids the body of the pathogen and do not produce any lasting effects. The prognosis for fevers associated with more chronic conditions, such as autoimmune disease, depends upon the overall outcome of the disorder.

Fever evaluation tests

Definition

Fever evaluation tests, better known as febrile agglutinins tests, are performed to detect the presence of antibodies in the blood that are sensitive to temperature changes. Antibodies are proteins produced by the immune system in response to specific infectious agents, such as viruses or bateria. Febrile agglutinins are antibodies that cause red blood cells to clump, but only when the blood is warmed to temperatures higher than the average body temperature of 98.6°F (37°C).

Purpose

The febrile agglutinins test is used to confirm the diagonsis of certain infectious diseases that stimulate the body to produce febrile agglutinins. The disease most commonly diagnosed by this test is **brucellosis**, a infection caused by bacteria belonging to the genus *Brucella* and characterized by intermittent fever, sweating, chills, aches, and mental depression. The test is also used to diagnose certain other infectious diseases: salmonellosis, caused by *Salmonella* bacteria and marked by nausea and severe **diarrhea**; rickettsial infections, a group of diseases caused by the bacteria *Rickettsia*; and **tularemia**, also called rabbit fever, a bacterial infection characterized by a high fever and swollen lymph nodes. The febrile agglutinins test can also be used to confirm the presence of two types of cancer, leukemia and lymphoma; however, doctors rarely use the test for this purpose, since other diagnostic tests are more reliable.

Description

A febrile agglutinins test can be performed at a doctor's office or a hospital. A nurse or technician will collect a few drops of blood (about 7 mL) in a small tube that has been cooled slightly. The specimen is then taken to a laboratory where it heated and examined for clumping. If the cells clump after warming and unclump as they cool, a febrile agglutinin titer (concentration) of greater than 1:80 is present.

Results

The results of febrile agglutinins tests require a doctor's interpretation. In general, however, a normal value is lower than 1:32.

Abnormal results

A value higher than 1:80 suggests a diagnosis for brucellosis or one of the other conditions indicated by this test.

Jill S. Lasker

Fever of unknown origin

Definition

Fever of unknown origin (FUO) refers to the presence of a documented fever for a specified time, for which a cause has not been found after a basic medical evaluation. The classic criteria developed in 1961 included: temperature greater than 101°F (38.3°C) for at least three weeks, and inability to find a cause after one week of study. Within the past decade, a revision has been proposed that categorizes FUO into classic, hospital acquired FUO, FUO associated with low white blood counts, and HIV associated FUO (**AIDS** related).

Description

Fever is a natural response of the body that helps in fighting off foreign substances, such as microorganisms, toxins, etc. Body temperature is set by the thermoregulatory center, located in an area in the brain called hypothalamus. Body temperature is not constant all day, but actually is lowest at 6 a.m. and highest around 4–6 p.m. In addition, temperature varies in different regions of the body; for example, rectal and urine temperatures are about one degree Fahrenheit

WWW.BOOKBAZ.IR

higher than oral temperature and rectal temperature is higher than urine. It is also important to realize that certain normal conditions can effect body temperature, such as **pregnancy**, food ingestion, age, and certain hormonal changes.

Substances that cause fever are known as "pyrogens." Pyrogens come in two types: exogenous and endogenous. Those that originate outside the body, such as bacterial toxins, are called "exogenous" pyrogens. Pyrogens formed by the body's own cells in response to an outside stimulus (such as a bacterial toxin) are called "endogenous" pyrogens.

Researchers have discovered that there are several endogenous pyrogens. These are made up of small groups of amino acids, the building blocks of proteins. These natural pyrogens have other functions in addition to inducing fever; they have been named "cytokines." When cytokines are injected into humans, fever and chills develop within an hour. Interferon, **tumor necrosis factor**, and various interleukins are the major fever producing cytokines.

The production of fever is a very complex process. Somehow, these cytokines cause the thermoregulatory center in the hypothalamus to reset the normal temperature level. The body's initial response is to conserve heat by vasoconstriction, a process in which blood vessels narrow and prevent heat loss from the skin and elsewhere. This alone will raise temperature by two to three degrees. Certain behavioral activities also occur, such as adding more clothes, seeking a warmer environment, etc. If the hypothalamus requires more heat, then shivering occurs.

Fever is a body defense mechanism. It has been shown that one of the effects of temperature increase is to slow bacterial growth. However, fever also has some downsides: The body's metabolic rate is increased and with it, oxygen consumption. This can have a devastating effect on those with poor circulation. In addition, fever can lead to seizures in the very young.

When temperature elevation occurs for an extended period of time and no cause is found, the term FUO is then used. The far majority of these patients are eventually found to have one of several diseases.

Causes and symptoms

The most frequent cause of FUO is still infection, though the percentage has decreased in recent years. **Tuberculosis** remains an important cause, especially when it occurs outside the lungs. The decrease in infections as a cause of FUO is due in part to improved culture techniques. In addition, technological advances have made it easier to diagnose non-infectious causes. For example, tumors and autoimmune diseases in particular are now easier to diagnose. (An autoimmune disease is one that arises when the body tolerance for its own cell antigenic cell markers disappears.)

Allergies to medications can also cause prolonged fever; sometimes patients will have other symptoms suggesting an allergic reaction, such as a rash.

FUO has many possible causes. Generally though, a diagnosis can be found. About 10% of patients will wind up without a definite cause, and about the same percentage have "factitious fevers" (either self-induced or no fever at all).

Some general symptoms tend to occur along with fever. These are called constitutional symptoms and consist of myalgias (muscle aches), chills, and **headache**.

Diagnosis

Few symptoms in medicine present such a diagnostic challenge as fever. Nonetheless, if a careful, logical, and thorough evaluation is performed, a diagnosis will be found in most cases. The patient's past medical history as well as travel, social, and family history should be carefully searched for important clues.

Usually the first step is to search for an infectious cause. Skin and other screening tests for diseases such as tuberculosis, and examination of blood, urine, and stool, are generally indicated. Antibody levels to a number of infectious agents can be measured; if these are rising, they may point to an active infection.

Various x-ray studies are also of value. In addition to standard examinations, recently developed radiological techniques using **ultrasound**, computed tomography scan (CT scan) and **magnetic resonance imaging** (MRI) scans are now available. These enable physicians to examine areas that were once accessible only through surgery. Furthermore, new studies using radioactive materials (nuclear medicine), can detect areas of infection and inflammation previously almost impossible to find, even with surgery.

Biopsies of any suspicious areas found on an x-ray exam can be performed by either traditional or newer surgical techniques. Material obtained by biopsy is then examined by a pathologist to look for clues as to the cause of the fever. Evidence of infection, tumor or other diseases can be found in this way. Portions of the biopsy are also sent to the laboratory for culture in an attempt to grow and identify an infectious organism.

KEY TERMS

AIDS—Acquired immune deficiency syndrome is often represented by these initials. The disease is associated with infection by the human immunodeficiency virus (HIV), and has the main feature of repeated infections, due to failure of certain parts of the immune system. Infection by HIV damages part of the body's natural immunity, and leads to recurrent illnesses.

Antibiotic—A medication that is designed to kill or weaken bacteria.

Computed tomography scan (CT Scan)—A specialized x-ray procedure in which cross-sections of the area in question can be examined in detail. This allows physicians to examine organs such as the pancreas, bile ducts, and others which are often the site of hidden infections.

Magnetic Resonance Imaging (MRI)—This technique is similar to CT Scan, but based on the magnetic properties of various areas of the body to compose images.

NSAID—Nonsteroidal anti-inflammatory drugs are medications such as aspirin and ibuprofen that decrease pain and inflammation. Many can now be obtained without a doctor's prescription.

Ultrasound—A non-invasive procedure based on changes in sound waves of a frequency that cannot be heard, but respond to changes in tissue composition. It is very useful for diagnosing diseases of the gallbladder, liver, and hidden infections, such as abscesses.

Patients with HIV are an especially difficult problem, as they often suffer from many unusual infections. HIV itself is a potential cause of fever.

Treatment

Most patients who undergo evaluation for FUO do not receive treatment until a clear-cut cause is found. **Antibiotics** or medications designed to suppress a fever (such as NSAIDs) will only hide the true cause. Once physicians are satisfied that the fever has no infectious cause, they may use medications such as NSAIDs, or **corticosteroids** to decrease inflammation and diminish constitutional symptoms.

The development of FUO in certain settings, such as that acquired by patients in the hospital or in those with a low white blood count, often needs rapid treatment to avoid serious complications. Therefore, in these instances patients may be placed on antibiotics after a minimal number of diagnostic studies. Once test results are known, treatment can be adjusted as needed.

Prognosis

The outlook for patients with FUO depends on the cause of the fever. If the basic illness is easily treatable and can be found rather quickly, the potential for a cure is quite good. Some patients continue with temperature elevations for six months or more. If no serious disease is found, medications such as NSAIDs are used to decrease the effects of the fever. Careful follow-up and reevaluation is recommended in these cases.

Fibrin degradation products *see* **Fibrin split products**

Fibrin split products

Definition

Fibrin split products (FSP) are fragments of protein released from a dissolving clot. The fibrin split products test is one of several tests done to evaluate a person with blood-clotting problems (coagulation), particularly disseminated intravascular coagulation (DIC).

Purpose

High levels of FSP in a person's blood are associated with DIC, a serious medical condition that develops when the normal balance between bleeding

WWW.BOOKBAZ.IR

KEY TERMS

Coagulation—The entire process of blood clotting.

Coagulation cascade—A sequence of biochemical activities to stop bleeding by forming a clot.

Disseminated intravascular coagulation (DIC)—A serious medical condition that develops when the normal balance between bleeding and clotting is disturbed. Excessive bleeding and clotting injures body organs, and causes anemia or death.

Fibrin split products (FSP)—Pieces of the protein fibrin released from a dissolving clot.

Fibrinolysis—The clot dissolving portion of the coagulation process.

Titer—A dilution of a substance with an exact known amount of fluid. For example, one part of serum diluted with four parts of saline is a titer of 1:4.

and clotting is disturbed. Excessive bleeding and clotting injures body organs, and causes anemia or death.

Description

Coagulation begins typically with an injury to some part of the body. The injury sets in motion a cascade of biochemical activities (the coagulation cascade) to stop the bleeding, by forming a clot from a mixture of the blood protein fibrin and platelets.

Once bleeding is stopped, another blood protein dissolves the clot by breaking down the fibrin into fragments. Measurement of these fragments gives information about the clot-dissolving portion of coagulation, called fibrinolysis.

In DIC, the coagulation cascade is triggered in an abnormal way. A blood infection, a **transfusion** reaction, a large amount of tissue damage, such as a burn, a dead fetus, and some cancers can begin the chain of biochemical events leading to **blood clots**. The coagulation cascade becomes overwhelmed with excessive clotting followed by excessive bleeding. As the large number of clots dissolve, fibrin split products accumulate in the blood and encourage even more bleeding.

Laboratory tests for FSP are done on the yellow liquid portion left over after blood clots (serum). A person's serum is mixed with a substance that binds to FSP. This bound complex is measured, and the original amount of FSP is determined. Some test methods give an actual measurement of FSP; some give a titer, or dilution. Methods that provide a titer look for the presence or absence of FSP. If the serum is positive for FSP, the serum is diluted, or titered, and the test is done again. These steps are repeated until the serum is so dilute that it no longer gives a positive result. The last dilution that gives a positive result is the titer reported.

The FSP test is covered by insurance when medically necessary. Results are usually available within one to two hours. Other names for this test are fibrin degradation products, fibrin breakdown products, or FDP.

Preparation

This test requires 0.17 oz (5/14 m) of blood. A healthcare worker ties a tourniquet on the patient's upper arm, locates a vein in the inner elbow region, and inserts a needle into that vein. Vacuum action draws the blood through the needle into an attached tube. Collection of the sample takes only a few minutes.

Aftercare

Discomfort or bruising may occur at the puncture site. Pressure applied to the puncture site until the bleeding stops reduces bruising. Warm packs to the puncture site relieve discomfort. The patient may feel dizzy or faint.

Risks

People with coagulation problems may bleed longer than normal. The healthcare provider must make sure bleeding has stopped before leaving the patient unattended.

Results

Negative at a less than or equal to 1:4 dilution or less than 10 g/mL.

Abnormal results

High levels of FSP indicate DIC. Results of the test must be interpreted by the physician according to the person's clinical symptoms and medical history. Other conditions that increase blood clotting activity

also increase FSP: venous thrombosis, surgery and transplants, blood clots in the lung, certain cancers, and **heart attack** (myocardial infarction).

Fibrinogen test

Definition

Fibrinogen (Factor I) is a protein that originates in the liver. It is converted to fibrin during the blood-clotting process (coagulation).

Purpose

The fibrinogen test aids in the diagnosis of suspected clotting or bleeding disorders caused by fibrinogen abnormalities.

Description

Fibrinogen plays two essential roles in the body: It is a protein called an acute-phase reactant that becomes elevated with tissue inflammation or tissue destruction, and it is also a vital part of the "common pathway" of the coagulation process.

In order for blood to clot, fibrinogen must be converted to fibrin by the action of an enzyme called thrombin. Fibrin molecules clump together to form long filaments, which trap blood cells to form a solid clot.

The conversion of fibrinogen to fibrin is the last step of the "coagulation cascade," a series of reactions in the blood triggered by tissue injury and platelet activation. With each step in the cascade, a coagulation factor in the blood is converted from an inactive to an active form. The active form of the factor then activates several molecules of the next factor in the series, and so on, until the final step, when fibrinogen is converted into fibrin.

The factors involved in the coagulation cascade are numbered I, II, and V through XIII. Factor I is fibrinogen, while factor II (fibrinogen's immediate precursor) is called prothrombin. Most of the coagulation factors are made in the liver, which needs an adequate supply of **vitamin K** to manufacture the different clotting factors.

When fibrinogen acts as an "acute-phase reactant," it rises sharply during tissue inflammation or injury. When this occurs, high fibrinogen levels may be a predictor for an increased risk of heart or circulatory disease. Other conditions in which fibrinogen is elevated are cancers of the stomach, breast, or kidney, and inflammatory disorders like **rheumatoid arthritis**.

Reduced fibrinogen levels can be found in **liver disease**, **prostate cancer**, lung disease, bone marrow lesions, malnourishment, and certain bleeding disorders. The low levels can be used to evaluate disseminated intravascular coagulation (DIS), a serious medical condition that develops when there is a disturbed balance between bleeding and clotting. Other conditions related to decreased fibrinogen levels are those in which fibrinogen is completely absent (congenital afibrinogenemia), conditions in which levels are low (hypofibrinogenemia), and conditions of abnormal fibrinogen (dysfibrinogenemia). Obstetric complications or **trauma** may also cause low levels. Large-volume blood transfusions cause low levels because banked blood does not contain fibrinogen.

Preparation

This test is performed with a blood sample, which can be drawn at any time of day. The patient does not have to be **fasting** (nothing to eat or drink).

Aftercare

Because a fibrinogen test is often ordered when a bleeding disorder is suspected, the patient should apply pressure or a pressure dressing to the blood-drawn site site for a period of time after blood is drawn, and then reexamine the site for bleeding.

Risks

Risks for this test are minimal, but may include slight bleeding from the blood-drawing site, **fainting** or feeling lightheaded after procedure, or the seeing the accumulation of blood under the puncture site (hematoma).

This test is not recommended for patients with active bleeding, acute infection or illness, or in those patients who have received blood transfusions within four weeks.

Drugs that may increase fibrinogen levels include estrogens and **oral contraceptives**. Drugs that may

WWW.BOOKBAZ.IR

KEY TERMS

Fibrin—The last step in the coagulation process. Fibrin forms strands that add bulk to a forming blood clot to hold it in place and help "plug" an injured blood vessel wall.

Platelet—An irregularly shaped cell-like particle in the blood that is an important part of blood clotting. Platelets are activated when an injury causes a blood vessel to break. They change shape from round to spiny, "sticking" to the broken vessel wall and to each other to begin the clotting process.

Prothrombin—A type of protein called a glycoprotein that is converted to thrombin during the clotting process.

Thrombin—An enzyme that converts fibrinogen into strands of fibrin.

cause decreased levels include anabolic **steroids**, androgens, phenobarbital, urokinase, streptokinase, and valproic acid.

Results

Normal reference ranges are laboratory-specific, but are usually within the following:

- adult: 200 mg/dL–400 mg/dL
- newborn: 125 mg/dL–300 mg/dL

Abnormal results

Spontaneous bleeding can occur with values less than 100 mg/dL.

Fibroadenoma

Definition

Fibroadenomas are benign breast tumors commonly found in young women. Fibroadenoma means "a tumor composed of glandular (related to gland) and fibrous (containing fibers) tissues."

Description

Breast fibroadenomas, abnormal growths of glandular and fibrous tissues, are most common between the ages of 15 and 30, and are found in 10% of all women (20% of African-American women). They are found rarely in postmenopausal women.

Described as feeling like marbles, these firm, round, movable, and "rubbery" lumps range from 1–5 cm in size. Giant fibroadenomas are larger, lemon-sized lumps. Usually single, from 10–15% of women have more than one.

While some types of breast lumps come and go during the menstrual cycle, fibroadenomas typically do not disappear after a woman's period, and should be checked by a doctor.

Causes and symptoms

The cause of breast fibroadenomas is unknown. They may be dependent upon estrogen, because they are common in premenopausal women, can be found in postmenopausal women taking estrogen, and because they grow larger in pregnant women.

Fibroadenomas usually cause no symptoms and may be discovered during **breast self-examination**, or during a routine check-up.

Diagnosis

When the doctor takes a complete medical history, they will ask when the lump was first noticed, if there were any symptoms or changes in lump size, and if there is any personal or family history of breast disease.

The doctor thoroughly feels the breasts (palpates). Tests are done, usually including **mammography** or **ultrasound** scans, or surgical removal of cells or tissue for examination under a the microscope (biopsy).

Diagnostic tests include:

- mammogram, an x-ray examination of the breast
- ultrasound scan, a technique that uses sound waves to display a two-dimensional image of the breast, showing whether a lump is solid or fluid-filled (cystic)
- fine-needle aspiration biopsy, a minor procedure wherein fluid or cells are drawn out of the lump through a small needle (aspirated)

KEY TERMS

Aspiration—To withdraw material with a needle and syringe.

Biopsy—To remove cells or tissue for microscopic examination.

Estrogen—Female sex hormone produced by the ovaries.

- core biopsy, a procedure wherein a larger piece of tissue is withdrawn from the lump through a larger needle
- incisional biopsy, a surgical procedure wherein a piece of the lump is removed through an cut (incision)
- excisional biopsy, a surgical procedure wherein the entire lump is removed through an cut (incision)

Most insurance plans cover the costs of diagnosing and treating fibroadenomas.

Treatment

Performed usually in outpatient settings, breast fibroadenomas are removed by **lumpectomy**, or surgical excision under local or general **anesthesia**. Sometimes lumps in younger women are not removed but are monitored by self-examination, yearly doctor check-ups, and mammograms. Surgery is generally recommended for women over 30, and for lumps that are painful or enlarging.

Alternatives

Alternative treatments for breast fibroadenomas include a low-fat, high-fiber, vegetarian-type diet; a reduction in **caffeine** intake; supplementation with evening primrose oil (Oenothera biennis), flax oil, or fish oil and **vitamins** E and C; and the application of hot compresses to the breast. In addition, a focus on liver cleansing is important to assist the body in conjugation and elimination of excess estrogens. Botanical remedies can be useful in hormone balancing, as can **acupuncture** and homeopathy. Massaging the breasts with castor oil, straight or infused with herbs or essential oils, can help fibroadenomas reduce and dissipate, as well as keep women in touch with changes in their breast tissue.

Prognosis

Breast fibroadenomas are not cancerous. The lumps recur in up to 20% of women. A small number of lumps disappear on their own.

Prevention

Breast fibroadenomas cannot be prevented. They can be discovered early by regular breast self-examination.

Fibrocystic breast disease *see* **Fibrocystic condition of the breast**

Fibrocystic condition of the breast

Definition

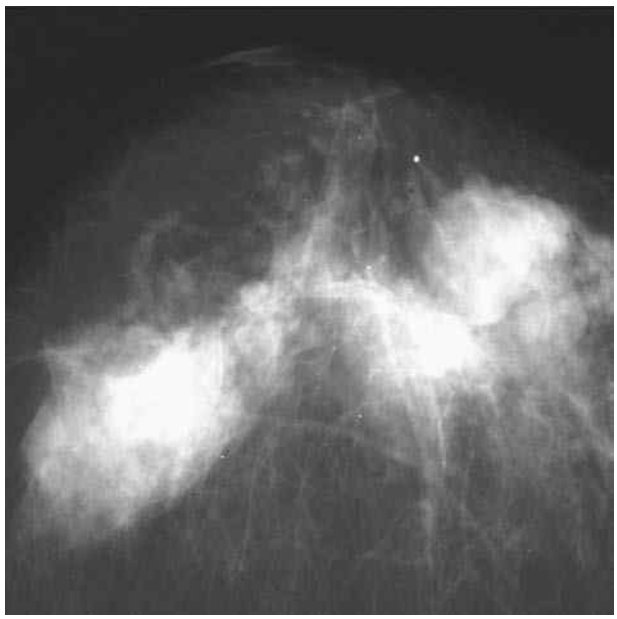
Fibrocystic condition of the breast is a term that may refer to a variety of symptoms: breast lumpiness or tenderness, microscopic breast tissue, and/or the x-ray or **ultrasound** picture of the breast. It has been called a "wastebasket" diagnosis because a wide range of vaguely defined benign breast conditions may be labeled as fibrocystic condition. It is not a cancer, and the majority of types of fibrocystic conditions do not increase the risk of **breast cancer**.

Description

There is no such thing as a normal or typical female breast. Breasts come in all shapes and sizes, with varying textures from smooth to extremely lumpy. The tissues of the female breast change in response to hormone levels, normal **aging**, nursing (**lactation**), weight fluctuations, and injury. To further complicate matters, the breast has several types of tissue; each of these tissue types may respond differently to changes in body chemistry.

Fibrocystic breast condition may be called fibrocystic disease, although it is clearly not a single, specific disease process. Variations or changes in the way the breast feels or looks on x ray may cause the condition to be called "fibrocystic change." Other names have been used to refer to this imprecise and ill-defined term: mammary dysplasia, mastopathy, chronic cystic **mastitis**, indurative mastopathy, mastalgia, lumpy breasts, or physiologic nodularity.

WWW.BOOKBAZ.IR



A mammogram of a female breast indicating multiple cysts. *(Custom Medical Stock Photo, Inc.)*

Estimates vary, but 40–90% of all women have some evidence of "fibrocystic" condition, change, or disease. It is most common among women between the ages 30 and 50, but may be seen at other ages.

Causes and symptoms

Fibrocystic condition of the breast refers to technical findings on diagnostic testing (signs); however, this discussion focuses on symptoms that may fall under the general category of the fibrocystic condition. First, a brief review of the structure and function of the breast may be useful.

The breast is not supposed to be a soft, smooth organ. It is actually a type of sweat gland. Milk, the breasts' version of sweat, is secreted when the breast receives appropriate hormonal and environmental stimulation.

The normal breast contains milk glands, with their accompanying ducts, or pipelines, for transporting the milk. These complex structures may not only alter in size, but can increase or decrease in number as needed. Fibrous connective tissue, fatty tissue, nerves, blood and lymph vessels, and lymph nodes, with their different shapes and textures, lie among the ever-changing milk glands. It is no wonder that a woman's breasts may not feel uniform in texture and that the "lumpiness" may wax and wane.

The fibrocystic condition refers to the tenderness, enlargement, and/or changing "lumpiness" that many women encounter just before or during their menstrual periods. At this time, female hormones are preparing the breasts for **pregnancy**, by stimulating the milk-producing cells, and storing fluid. Each breast may contain as much as three to six teaspoons of excess fluid. Swelling, with increased sensitivity or **pain**, may result. If pregnancy does not occur, the body reabsorbs the fluid, and the engorgement and discomfort are relieved.

Symptoms of fibrocystic breast condition range from mildly annoying in some women to extremely painful in others. The severity of discomfort may vary from month to month in the same woman. Although sometimes distressing, this experience is the body's normal response to routine hormonal changes.

This cycle of breast sensitivity, pain and/or enlargement, can also result from medications. Some hormone replacement therapies (estrogen and progesterone) used for postmenopausal women can produce these effects. Other medications, primarily, but not exclusively those with hormones may also provoke these symptoms.

Breast pain unrelated to hormone shifts is called "noncyclic" pain. "Trigger-zone breast pain" is a term that may also be used to describe this area-specific pain. This type of pain may be continuous, or it may be felt intermittently. **Trauma**, such as a blow to the chest area, a prior **breast biopsy**, or sensitivity to certain medications may also underlie this type of pain. Fibrocystic condition of the breast may be cited as the cause of otherwise unexplained breast pain.

Lumps, apart from those clearly associated with hormone cycles, may also be placed under the heading of fibrocystic condition. These lumps stand out from enlarged general breast tissue. Although noncancerous lumps may occur, the obvious concern with such lumps is cancer.

Noncancerous breast lumps include:

- Adenosis. This condition refers to the enlargement of breast lobules, which contain a greater number of glands than usual. If a group of lobules are found near each other, the affected area may be large enough to be felt.
- Cysts. These are fluid-filled sacs in the breast and probably develop as ducts that become clogged with old cells in the process of normal emptying and

filling. Cysts usually feel soft and round or oval. However, a cyst deep within the breast may feel hard, as it pushes up against firmer breast tissue. A woman with a cyst may experience pain, especially if it increases in size before her menstrual cycle, as is often the case. Women between the age of 30 and 50 are most likely to develop cysts.

- Epithelial hyperplasia. Also called proliferative breast disease, this condition refers to an overgrowth of cells lining either the ducts or the lobules.
- Fibroadenomas. These are tumors that form in the tissues outside the milk ducts. The cause of fibroadenomas is unknown. They generally feel smooth and firm, with a somewhat rubber-like texture. Typically a fibroadenoma is not attached to surrounding tissue and moves slightly when touched. They are most commonly found in adolescents and women in their early twenties but can occur at any age.
- Fibrosis. Sometimes one area of breast tissue persistently feels thicker or more prominent than the rest of the breast. This feeling may be caused by old hardened scar tissue and/or dead fat tissue as a result of surgery or trauma. Often the cause of this type of breast tissue is unknown.
- Miscellaneous disorders. A number of other benign (noncancerous) breast problems may be placed under the heading of "fibrocystic condition." These problems include disorders that may lead to breast inflammation (mastitis), infection, and/or nipple discharge.

Atypical ductal hyperplasia

Known as atypical ductal hyperplasia (ADH), this is a condition in which the cells lining the milk ducts of the breast are growing abnormally. This condition may appear as spots of **calcium** salts, or calcifications, on the mammogram. A biopsy removed from the breast would confirm the diagnosis. Atypical ductal hyperplasia is not a cancer. In most women, this condition will cause no problems. However, for some women, especially women with family histories of breast cancer, the risk of developing breast cancer is increased. (One study with more than 3,000 female participants indicated that about 20% of the participants who had atypical hyperplasia and a family history of breast cancer, developed breast cancer, as compared to the 8% of participants who developed the disease with atypical hyperplasia and no family history of breast cancer.) For women with ADH and a family history of breast cancer, more frequent mammograms and closer monitoring may be required.

Diagnosis

Breast cancer is the most common concern of women who feel a breast lump or experience an abnormal breast symptom. For peace of mind, and to rule out any possibility of cancer, any newly discovered breast lumps should be brought to the attention of a family physician or an obstetrician-gynecologist. He or she will obtain a history and conduct thorough **physical examination** of the area. Depending on the findings of the physical examination, the patient is usually referred for tests. The most common of these tests include:

- Mammography. A mammogram is an x-ray examination of the breasts. The two major types of abnormalities doctors look for are masses and calcifications; either abnormality may be benign or malignant. The size, shape, and edges of these masses help doctors determine whether or not cancer is present. Sometimes, however, this test may be difficult to interpret, however, due to dense breast tissue.
- Ultrasonography. If a suspicious lump is detected during mammography, an ultrasound (the use of high-frequency sound waves to outline the shape of various organs and tissues in the body) is useful (although not definitive) in distinguishing benign from cancerous growths.
- Ductography. A ductogram (also called a galactogram) is a test that is sometimes useful in evaluating nipple discharge. A very fine tube is threaded into the opening of the duct onto the nipple. A small amount of dye is injected, outlining the shape of the duct on an x ray, and indicates whether or not there is a mass in the duct.
- Biopsy. If a lump cannot be proven benign by mammography and ultrasound, a breast biopsy may be considered. Usually a tissue sample is removed through a needle (fine-needle aspiration biopsy, or FNAB) to obtain a sample of the lump. The sample is examined under the microscope by a pathologist, and a detailed diagnosis regarding the type of benign lesion or cancer is established. In some cases, however, FNAB may not provide a clear diagnosis, and another type of biopsy (such as a surgical biopsy, core-needle biopsy, or other stereotactic biopsy methods—such as the mammotome or advanced breast biopsy instrument) may be required.

Other breast conditions such as inflammation or infection are usually recognized on the basis of suspicious history, **breastfeeding**, or characteristic symptoms such as pain, redness, and swelling. A positive

WWW.BOOKBAZ.IR

KEY TERMS

Advanced Breast Biopsy Instrument (ABBI)—Uses a rotating circular knife and thin heated electrical wire to remove a large cylinder of abnormal breast tissue.

Lobules—A small lobe or subdivision of a lobe (often on a gland) that may be seen on the surface of the gland by bumps or bulges.

Lymph nodes—Rounded, encapsulated bodies consisting of an accumulation of lymphatic tissue.

Mammotome—A method for removing breast biopsies using suction to draw tissue into an opening in the side of a cylinder inserted into the breast tissue. A rotating knife then cuts tissue samples from the rest of the breast; also known as a vacuum-assisted biopsy.

Stereotactic biopsy—A biopsy taken by precisely locating areas of abnormal growth through the use of delicate instruments.

response to appropriate therapies often confirms the diagnosis.

Treatment

Once a specific disorder within the broad category of fibrocystic condition is identified, treatment can be prescribed. There are a number of treatment options for women with a lump that has been diagnosed as benign. If it is not causing a great deal of pain, the growth may be left in the breast. However, some women may choose to have a lump, such as a **fibroadenoma**, surgically removed, especially if it is large. Another option to relieve the discomfort of a painful benign lump is to have the cyst suctioned, or drained. If there is any uncertainty regarding diagnosis, the fluid may be sent to the lab for analysis.

Symptoms of cycle breast sensitivity and engorgement may also be treated with diet, medication, and/or physical modifications. For example,

- Although no scientific data is available to support this claim, many women have reported relief of symptoms when caffeine was reduced or eliminated from their diets. Decreasing salt before and during the period when breasts are most sensitive may also ease swelling and discomfort. Low-fat diets and elimination of dairy products also appear to decrease soreness for some women. However, it may take several months to realize the effects of these various treatments.
- Over-the-counter analgesics such as acetaminophen (Tylenol) or ibuprofen (Advil) may be recommended. In some cases, treatment with prescription drugs such as hormones or hormone blockers may prove successful. Oral contraceptives may also be prescribed.
- Warm soaks or ice packs may provide comfort. A well-fitted support bra can minimize physical movement and do much to relieve breast discomfort. Breast massage may promote removal of excess fluid from tissues and alleviate symptoms. Massaging the breast with castor oil, straight or infused with herbs or essential oils, can help reduce and dissipate fibroadenomas as well as keep women in touch with changes in their breast tissue.
- Infections are often treated with warm compresses and antibiotics. Lactating women are encouraged to continue breastfeeding because it promotes drainage and healing. However, a serious infection may progress to form an abscess that may need surgical drainage.
- Some studies of alternative or complementary treatments, although controversial, have indicated that vitamins A, B complex and E, and mineral supplements may reduce the risk of developing fibrocystic condition of the breast. Evening primrose oil (*Oenothera biennis*), flaxseed oil, and fish oils have been reported to be effective in relieving cyclic breast pain for some women.

Prognosis

Most benign breast conditions carry no increased risk for the development of breast cancer. However, a small percentage of biopsies uncover overgrowth of tissue in a particular pattern in some women; this pattern indicates a 15–20% increased risk of breast cancer over the next 20 years. Strict attention to early detection measures, such as annual mammograms, is especially important for these women.

Prevention

There is no proven method of preventing the various manifestations of fibrocystic condition from occurring. Some alternative health care practitioners believe that eliminating foods high in methyl xanthines (primarily coffee and chocolate) can decrease or reverse fibrocystic breast changes.

Fibroids *see* **Uterine fibroids**

Fibromyalgia

Definition

Fibromyalgia is an inflammation of the fibrous or connective tissue (muscles, joints, ligaments, and tendons) of the body. It is characterized by muscle **pain**, **fatigue**, and multiple tender points on the body. Many individuals with fibromyalgia describe the symptoms as similar to the aches and pains of a severe case of the flu. Fibrositis, and fibromyositis are names given to a set of symptoms believed to be caused by the same general problem.

Description

Fibromyalgia is more common than was once thought. According to the American College of Rheumatology, as many as 2–4% of the U.S. population may be affected by the disorder. Fibromyalgia is more prevalent in adults than children, with more women affected than men, particularly women of childbearing age.

KEY TERMS

Connective tissue—Tissue that supports and binds other body tissue and parts.

Lyme disease—An acute recurrent inflammatory disease involving one or a few joints, believed to be transmitted by a tick-borne virus. The condition was originally described in the community of Lyme, Connecticut, but has also been reported in other parts of the United States and other countries. Knees and other large joints are most commonly involved with local inflammation and swelling.

Rheumatology—The study of disorders characterized by inflammation, degeneration of connective tissue, and related structures of the body. These disorders are sometimes collectively referred to as rheumatism.

Causes and symptoms

The exact cause of fibromyalgia is not known. Sometimes it occurs in several members of a family, suggesting that it may be an inherited disorder. Researchers have investigated a number of possible causes, including genetic causes, **sleep disorders**, specific injuries, infections, problems with muscle metabolism, problems with the neurons that transmit information about pain, and nervous system abnormalities. Research is frequently unable to determine if a specific problem, such as sleep disturbances, results from fibromyalgia or are a possible cause of the condition. It is likely that a number of factors must occur in combination to cause fibromyalgia.

Pain is the major symptom with aches, tenderness, and stiffness of multiple muscles, joints, and soft tissues. The pain may move from one part of the body to another. It is most common in the neck, shoulders, chest, arms, legs, hips, and back. Although the pain is present most of the time and may last for years, the severity of the pain may fluctuate.

Symptoms of fatigue may result from the individual's chronic pain coupled with **anxiety** about the problem and how to find relief. The inflammatory process also produces chemicals that are known to cause fatigue. Other common symptoms are tension headaches, difficulty swallowing, recurrent abdominal pain, **diarrhea**, and numbness or tingling of the extremities. **Stress**, anxiety, depression, or lack of sleep can increase symptoms. Intensity of symptoms

WWW.BOOKBAZ.IR

is variable, ranging from gradual improvement to episodes of recurrent symptoms.

Diagnosis

Diagnosis is difficult and frequently missed because symptoms of fibromyalgia are vague and generalized. Coexisting nerve and muscle disorders such as **rheumatoid arthritis**, spinal arthritis, or **Lyme disease** may further complicate the diagnostic process. As of 2014, no tests were available to specifically diagnose fibromyalgia. The diagnosis is usually made after ruling out other medical conditions with similar symptoms such as lupus and **hypothyroidism**.

Because of the emotional distress experienced by people with this condition and the influence of stress on the symptoms themselves, fibromyalgia has often been labeled a psychological problem. Although the debate about fibromyalgia continues, research on possible causes of the condition and public awareness campaigns have helped promote fibromyalgia's validity as a physiological problem.

The American College of Rheumatology has developed standards for fibromyalgia that healthcare practitioners can use to diagnose this condition. According to these standards, individuals can be diagnosed with fibromyalgia if they have widespread pain in combination with tenderness in at least 11 of the 18 sites known as trigger points. Trigger point sites include the base of the neck, along the backbone, in front of the hip and elbow, and at the rear of the knee and shoulder.

Treatment

Fibromyalgia has no known cure. Therefore, the goal of treatment is successful symptom management. Treatment usually requires a combination of therapies, including medication, **exercise**, and lifestyle adjustments. On June 21, 2007, the U.S. Food and Drug Administration (FDA) approved the first drug to treat fibromyalgia. Although previously many doctors had prescribed a variety of medications intended to help reduce the symptoms of fibromyalgia, Lyrica (pregabalin) was the first drug approved specifically for the treatment of fibromyalgia. Made by Pfizer, Lyrica was already used to treat pain associated with nerve damage caused by diabetes, pain following **shingles**, and partial seizures. A study of 1,800 patients showed that Lyrica was also effective in treating the pain associated with fibromyalgia in many people. Lyrica was not found to be effective in everyone with fibromyalgia, however, and it can have side effects, including sleepiness, **dizziness**, weight gain, swelling of the feet and hands, blurred vision, and **dry mouth**.

In addition to treatment with medication there are many other ways of managing the symptoms of fibromyalgia. Adequate rest is essential, as is a healthy diet. The diet should include a large variety of fruits and vegetables, which provide the body with trace elements and **minerals** that are necessary for healthy muscles. Avoidance of stimulating foods or drinks (such as coffee) and medications such as **decongestants** prior to bedtime is advised. Individuals should have a clear understanding of their role in the recovery process because it determines the successful management of this condition.

Other treatments found to be helpful include heat and occasionally cold-compress applications. A regular stretching program is often useful. Aerobic activities focusing on increasing the heart rate are the preferred forms of exercise over most other forms of exertion. Exercise programs need to include good warm-up and cool-down sessions, with special attention given to avoiding exercises causing joint pain. **Hydrotherapy** exercises (exercises in a pool or tub) may be useful in providing a low-impact exercise environment while soothing muscle and joint pain.

Massage therapy can be helpful, especially when a family member is instructed on specific massage techniques to manage episodes of increased symptoms. Short sessions are most helpful as repetitious movement can aggravate the condition. Specific attention to mental health, including psychological treatment, may also be important, since depression may precede or accompany fibromyalgia. Relaxation exercises, **yoga**, **aromatherapy**, **guided imagery**, and other relaxation therapies can be useful in easing stress and promoting overall well-being. A Mayo Clinic study released in 2006 found that **acupuncture** can be helpful in relieving the symptoms of fibromyalgia.

Herbalists and aromatherapists may recommend tub soaks or compresses with lavender (*Lavandula angustifolia*), chamomile (*Chamaemelum nobilis*), or juniper (*Juniperus communis*) to soothe muscle and joint pain.

Alternatives

People with fibromyalgia often need a rheumatology consultation (a meeting with a doctor who specializes in disorders of the joints, muscles, and soft tissue) to decide the cause of various rheumatic symptoms, to be educated about fibromyalgia and its treatment, and to exclude other rheumatic diseases.

A treatment program must be individualized to meet the patient's needs. The rheumatologist, as the team leader, enlists and coordinates the expertise of other health professionals in the care of the patient.

Prognosis

Fibromyalgia is a chronic health problem. The symptoms sometimes improve and at other times worsen, but they often continue for months to years.

Fibromyalgia can be a stressful and frustrating condition for a majority of patients. Successful treatment often requires a period of trial and error to pinpoint which agents and activities work best for the individual. Support from a health care team and coordination of care through follow-up calls to outside health care providers may be beneficial.

Clinical parameters are **pain management**, improved sleep management, introduction of relaxation techniques (including massage and **biofeedback** if needed), and monitoring alternative treatments and medication. Education is an integral part of the treatment and management of fibromyalgia and its symptoms.

A wide variety of health care providers may be involved in an individual's care, including nurses, physicians, a rheumatologist or other subspecialist, nutritionist, physical therapist, alternative medicine caregiver, or mental health care provider.

Prevention

No known or specific prevention for fibromyalgia exists. However, similar to many other medical conditions, remaining as healthy as possible with a good diet, safe exercise, and adequate rest is the best prevention.

Fibromyomas *see* **Uterine fibroids**

Fibrosis

Definition

Fibrosis is a medical term that refers to the excessive growth of fibrous, scar-like connective tissue in some part of the body.

Description

Fibrosis can occur in many organs, including the lungs, heart, liver, joints, and skin. Some fibroses have an inherited component. Others develop for no known reason (idiopathic fibrosis). Fibroses in the lung (pulmonary fibroses) often develop from prolonged environmental exposure to dust and chemicals.

Respiratory fibroses are one of the more common and serious types of fibrosis. Pulmonary fibrosis develops when the alveoli, tiny air sacs that transfer oxygen to the blood, become damaged and inflamed. The

WWW.BOOKBAZ.IR

body tries to heal the damage with scar tissue, but these scars collapse the alveoli and make the lungs less elastic. If the cycle of inflammation and scarring continues, the lungs become increasingly rigid and unable to deliver oxygen to the blood.

Pulmonary fibrosis can result from sarcoidosis, drug reactions, autoimmune diseases, environmental allergies such as Farmer's lung, and exposure to toxic dusts and gases. A number of respiratory fibroses, including such conditions as black lung disease, silicosis, **asbestosis**, **berylliosis**, and **byssinosis**, are linked to specific environmental exposures. Pulmonary fibrosis that develops without a known cause is called idiopathic pulmonary fibrosis. This disease is equally common in men and women. It is usually diagnosed between the ages of 40 and 60.

Causes and symptoms

The causes and risk factors vary with the underlying disease. They may include genetic factors, environmental factors, and infections. In the case of environmental factors, a fibrosis develops when a person inhales very tiny solid particles or liquid droplets over many years or decades. Part of the body's reaction to these foreign particles is to enmesh them in fibrous tissue. The disease name usually suggests the agent that causes the disease. Silicosis, for example, is caused by the inhalation of silica, tiny sand-like particles. Occupational sources of silicosis include rock mining, quarrying, stone cutting, and sandblasting. Berylliosis is caused by the inhalation of beryllium particles over time, and byssinosis (from byssos, the Greek word for flax) is found among textile workers who inhale flax, cotton, or hemp fibers.

The first symptom of pulmonary fibrosis usually is shortness of breath, at first, during exercise, but later also while resting. Individuals may also have a dry cough, rapid heartbeat, or enlargement of the fingertips and ends of the toes. Some people feel tired or have a fever, weight loss, muscle or joint pains. In late stages of the disease, the lack of oxygen in the blood can give the skin and mucus membranes a blue tinge known as **cyanosis**.

Diagnosis

Pulmonary fibrosis is often diagnosed and treated by a lung specialist. Several tests usually are needed to diagnose this disease and determine its cause. They include a physical examination, detailed history of the symptoms, chest x rays, lung function tests, and blood tests, including a measurement of the amount of oxygen in the blood. Computed tomography (CT scan) may give a more detailed picture of the lungs. Bronchoscopy may be done to examine the air passages and analyze the cells found deep in the lungs.

Lung biopsies are necessary to diagnose some diseases. Lung biopsies can be done through a needle inserted into the chest through the skin, during bronchoscopy, or as a surgical procedure under general anesthesia.

Treatment

The treatment of pulmonary fibrosis depends on the underlying cause. Many diseases are treated by suppressing inflammation with corticosteroids. Stronger immune suppressants such as cyclophosphamide (Cytoxan) or azathioprine (Imuran) may also be tried. Some patients need supplemental oxygen. A lung transplant may be an option for incurable diseases. Approximately 60–80% of patients live for at least two years after the transplant.

There is no good treatment for idiopathic pulmonary fibrosis. Only 10–20% of patients with this disease respond to corticosteroids.

Alternatives

Anxiety and fear can make breathing difficulties worse. Some patients find that activities such as yoga, prayer or meditation, music therapy, or biofeedback help to relax them.

Prognosis

Prognosis depends on the specific disease. Some cases may stop progressing or improve, particularly if the cause can be identified and treated. Others may develop quickly or slowly into end-stage lung disease. The course of idiopathic pulmonary fibrosis is very difficult to predict; however, average survival is approximately five to seven years.

Prevention

There is no known prevention for idiopathic pulmonary fibrosis.

The Occupational Safety and Health Administration sets standards for exposure to particulate matter and toxic chemical gasses in the workplace. The Environmental Protection Agency sets air pollution standards as well.

Some ways to prevent other environmental causes of pulmonary fibrosis are:

- avoid exposure to particle dust such as asbestos, coal dust, and silica.

KEY TERMS

Alveoli—Tiny air sacs in the lungs where oxygen and carbon dioxide are exchanged with the blood.

Autoimmune disease—A disease that develops when the immune system attacks normal cells or organs.

Bronchoscopy scan—The examination of the air passages through a flexible or rigid tube inserted into the nostril or mouth. Sometimes cells are collected by washing the lungs with a small amount of fluid.

Computed tomography (CT)—A special x-ray technique that produces a cross sectional image of the organs inside the body.

Corticosteroids—A class of drugs, related to hormones naturally found in the body, that suppress the immune system. One example is prednisone, sold under many brand names, including Deltasone.

End-stage lung disease—The final stages of lung disease, when the lung can no longer keep the blood supplied with oxygen. End-stage lungs in pulmonary fibrosis have large air spaces separated by bands of inflammation and scarring.

Farmer's lung—An allergic reaction to moldy hay, most often seen in farmers, that results in lung disease.

Inflammation—The body's reaction to an irritant, characterized by the accumulation of immune cells, redness, and swelling.

Lung function tests—Tests of how much air the lungs can move in and out, and how quickly and efficiently this can be done. Lung function tests are usually done by breathing into a device that measures air flow.

Sarcoidosis—A disease of unknown origin that results in clumps of immune cells and inflammation in organs throughout the body.

- avoid exposure to chemical fumes at work and during hobby activities
- do not smoke

Fibrous breast lumps *see* **Fibroadenoma**

Fifth disease

Definition

Fifth disease is a mild childhood illness caused by the human parvovirus B19 that causes flu-like symptoms and a rash.

Demographics

Anyone can get the disease, but it occurs more frequently in school-aged children. Outbreaks most often occur in the winter and spring, peaking every four to seven years. About 60% of adults have had the disease by age 20.

Description

Fifth disease got its name because it was fifth on a list of common childhood illnesses that are accompanied by a rash, including **measles**, **rubella** or German measles, **scarlet fever** (or scarlatina), and scarlatinella, a variant of scarlet **fever**. The Latin name for the disease is *erythema infectiosum*, meaning infectious redness. It is also called the "slapped cheek disease" because, when the bright red rash first appears on the cheeks, it looks as if the face has been slapped. The disease is usually mild, and both children and adults normally recover quickly without complications. In fact, some individuals exhibit no symptoms and never feel ill.

WWW.BOOKBAZ.IR

This infant has a rash caused by Fifth disease, or *erythema infectiosum*. *(Custom Medical Stock Photo, Inc.)*

Causes and symptoms

Fifth disease is caused by the human parvovirus B19, a member of the Parvoviridae family of viruses that lives in the nose and throat of the infected person. The virus is spread through the air by coughing and sneezing. Because the virus needs a rapidly dividing cell in order to multiply, it attacks the red blood cells of the body. Once infected, a person is believed to be immune to re-infection.

Symptoms appear four to 21 days after exposure to the virus. Initial symptoms are flu-like and include **headache**, body ache, **sore throat**, a mild fever of 101°F (38.3°C), and chills. It is at this time, before development of the rash, that individuals are contagious. These symptoms last for two to three days. In children, a bright red rash that looks like a slap mark develops suddenly on the cheeks. The rash may be flat or raised and may or may not be itchy. Sometimes, the rash spreads to the arms, legs, and trunk, where it has a lace-like or net-like appearance. The rash can also involve the palms of the hands and soles of the feet. By the time the rash appears, individuals are no longer infectious. On average, the rash lasts for 10–11 days, but may last for as long as five to six weeks. The rash may fade away and then reappear upon exposure to sunlight, hot baths, emotional distress, or vigorous **exercise**.

Adults generally do not develop a rash, but instead may have swollen and painful joints, especially in the hands and feet. In adults, symptoms such as sore throat, headache, muscle and joint **pain**, abdominal pain, **diarrhea**, and **vomiting** occur more frequently than in children and usually are more severe. Joint pain can be arthritis-like and last for several months, especially in women, but the disease does not appear to progress to **rheumatoid arthritis**.

The virus causes the destruction of red blood cells; therefore, a deficiency in the oxygen-carrying capacity of the blood (anemia) can result. In healthy people, the anemia is mild and lasts only a short while. In people with weakened immune systems, either because they have a chronic disease such as HIV infection/AIDS or cancer and are immunocompromised; or they are receiving medication to suppress the immune system and are therefore immunosuppressed (e.g., organ transplant recipients), this anemia can be severe and last long after the infection has subsided. Symptoms of anemia include **fatigue**, lack of healthy color, lack of energy, and **shortness of breath**. Some individuals with **sickle cell disease**, iron deficiency, a number of different hereditary blood disorders, and those who have received bone marrow transplantations may be susceptible to developing a potentially life-threatening complication called a transient aplastic crisis, in which the body is temporarily unable to form new red blood cells.

In very rare instances, the virus can cause inflammation of different areas of the body, including the brain (encephalitis), the covering of the brain and spinal cord (**meningitis**), the lungs (pneumonitis), the liver (hepatitis), and the heart muscle (**myocarditis**). The virus also can aggravate symptoms for people with an autoimmune disease called **systemic lupus erythematosus** (SLE).

Some concern surrounds fifth disease in pregnant women. Although no association with an increased number of **birth defects** or intellectual disabilities (ID) has been demonstrated, there is concern that infection during the first three months of **pregnancy** may slightly increase the risk of **miscarriage**. Some concern also exists that infection later in pregnancy may involve a very small risk of premature delivery or **stillbirth**. As a result, women who get fifth disease while they are pregnant should be monitored closely by a physician.

Diagnosis

Examination

Fifth disease usually is suspected based on a patient's symptoms, including the typical appearance

KEY TERMS

Anemia—A congenital or acquired deficiency in the iron–carrying capacity of the blood.

Antibody—A specific protein produced by the immune system in response to a specific foreign protein or particle called an antigen.

Immunocompromised—A state in which the immune system is weakened or is not functioning properly due to chronic disease.

Immunosuppressed—A state in which the immune system is suppressed by medications during the treatment of other disorders, such as cancer, or following an organ transplantation.

Reye's syndrome—A very serious, rare disease, most common in children, that involves an upper respiratory tract infection followed by brain and liver damage.

Sickle cell disease—A hereditary blood disorder in which red blood cells are misshapen into crescent or sickle shapes resulting in a reduced oxygen–carrying capacity of the lungs.

Systemic lupus erythematosus (SLE)—A chronic, inflammatory, autoimmune disorder in which the individual's immune system attacks, injures, and destroys the body's own organs and tissues. It may affect many organ systems including the skin, joints, lungs, heart, and kidneys.

of the bright red rash on the cheeks, patient history, age, and time of year. The physician will exclude other potential causes for the symptoms and rash, including rubella, **infectious mononucleosis**, bacterial infections such as **Lyme disease**, allergic reactions, and SLE.

Tests

In addition, a blood test is available for fifth disease, but it is generally used only for pregnant women and for people who have weakened immune systems or who have blood disorders, such as sickle cell disease. The test involves measuring for a particular antibody or protein that the body produces in response to infection with the human parvovirus B19. The test is 92–97% specific for this disease.

Because fifth disease can pose problems for an unborn fetus exposed to the disease through the mother, testing may also be conducted while a fetus is still in the uterus. This test uses fluid collected from the sac around the fetus (amniotic fluid) instead of blood to detect the viral DNA.

Treatment

In general, no specific treatment for fifth disease is required. The symptoms can be treated using over–the counter medications, such as **acetaminophen** (Tylenol) or ibuprofen (Motrin, Advil). If the rash itches, calamine lotion can be applied. **Aspirin** is not given to children under the age of 18 to prevent the development of a serious illness called Reye's syndrome.

Patients who are receiving medications to suppress the immune system in the treatment of some other condition may be allowed to temporarily decrease the medications in order to allow the immune system to combat the infection and recover from the anemia. Those with weakened (not suppressed) immune systems, such as HIV/AIDS patients, may be given immunoglobulin intravenously to help the immune system fight the infection. People with severe anemia or who experience an aplastic crisis may require hospitalization and blood transfusions.

Prognosis

Generally, fifth disease is mild, and patients tend to improve without any complications. In cases where the patient is either immunocompromised or immunosuppressed, a life–threatening aplastic crisis can occur. With prompt treatment, however, the prognosis is good. Mothers who develop the infection while pregnant can pass the infection on to their fetus, and as such, stand a very small increased risk of miscarriage and stillbirth. Tests and treatments, however, can be performed on the fetus while still in the uterus that can reduce the risk of anemia or other complications.

Prevention

Currently, there is no vaccine against fifth disease. Because people with fifth disease are contagious before definitive symptoms appear, it is very difficult to prevent infection. Avoiding contact with persons who exhibit symptoms of a cold and maintaining good personal hygiene by regularly washing hands may minimize the chances of an infection. Pregnant women should avoid exposure to persons infected with the disease and notify their obstetrician immediately if they are exposed so that they can be tested and monitored closely.

REVISED BY TISH DAVIDSON, AM

Filariasis

Definition

Filiariasis is the name for a group of tropical diseases caused by various thread-like parasitic round worms (nematodes) and their larvae. The larvae transmit the disease to humans through a mosquito bite. Filariasis is characterized by **fever**, chills, **headache**, and **skin lesions** in the early stages and, if untreated, can progress to include gross enlargement of the limbs and genitalia in a condition called **elephantiasis**.

Description

Approximately 170 million people in the tropical and subtropical areas of Southeast Asia, South America, Africa, and the islands of the Pacific are affected by this debilitating parasitic disease. While filariasis is rarely fatal, it is the second leading cause of permanent and long-term disability in the world. The World Health Organization (WHO) has named filariasis one of only six "potentially eradicable" infectious diseases and has embarked upon a 20-year campaign to eradicate the disease.

In all cases, a mosquito first bites an infected individual then bites another uninfected individual, transferring some of the worm larvae to the new host. Once within the body, the larvae migrate to a particular part of the body and mature to adult worms. Filariasis is classified into three distinct types according to the part of the body that becomes infected: lymphatic filariasis affects the circulatory system that moves tissue fluid and immune cells (lymphatic system); subcutaneous filariasis infects the areas beneath the skin and whites of the eye; and serous cavity filariasis infects body cavities but does not cause disease. Several different types of worms can be responsible for each type of filariasis, but the most common species include the following: *Wucheria bancrofti, Brugia malayi* (lymphatic filariasis), *Onchocerca volvulus, Loa loa, Mansonella streptocerca, Dracunculus medinensis* (subcutaneous filariasis), *Mansonella pustans*, and *Mansonella ozzardi* (serous cavity filariasis).

The two most common types of the disease are Bancroftian and Malayan filariasis, both forms of lymphatic filariasis. The Bancroftian variety is found throughout Africa, southern and southeastern Asia, the Pacific islands, and the tropical and subtropical regions of South America and the Caribbean. Malayan filariasis occurs only in southern and southeastern Asia. Filariasis is occasionally found in the United States, especially among immigrants from the Caribbean and Pacific islands.

A larvae matures into an adult worm within six months to one year and can live between four and six years. Each female worm can produce millions of larvae, and these larvae only appear in the bloodstream at night, when they may be transmitted, via an insect bite, to another host. A single bite is usually not enough to acquire an infection, therefore, short-term travelers are usually safe. A series of multiple bites over a period of time is required to establish an infection. As a result, those individuals who are regularly active outdoors at night and those who spend more time in remote jungle areas are at an increased risk of contracting the filariasis infection.

Causes and symptoms

In cases of lymphatic filariasis, the most common form of the disease, the disease is caused by the adult worms actually living in the lymphatic vessels near the lymph nodes where they distort the vessels and cause local inflammation. In advanced stages, the worms can actually obstruct the vessels, causing the surrounding tissue to become enlarged. In Bancroftian filariasis, the legs and genitals are most often involved,

while the Malayan variety affects the legs below the knees. Repeated episodes of inflammation lead to blockages of the lymphatic system, especially in the genitals and legs. This causes the affected area to become grossly enlarged, with thickened, coarse skin, leading to a condition called elephantiasis.

In conjunctiva filariasis, the worms' larvae migrate to the eye and can sometimes be seen moving beneath the skin or beneath the white part of the eye (conjunctiva). If untreated, this disease can cause a type of blindness known as onchocerciasis.

Symptoms vary, depending on what type of parasitic worm has caused the infection, but all infections usually begin with chills, headache, and fever between three months and one year after the insect bite. Swelling, redness, and **pain** may also occur in the arms, legs, or scrotum. Areas of pus (abscesses) may appear as a result of dying worms or a secondary bacterial infection.

Diagnosis

The disease is diagnosed by taking a patient history, performing a **physical examination**, and by screening blood specimens for specific proteins produced by the immune system in response to this infection (antibodies). Early diagnosis may be difficult because, in the first stages, the disease mimics other bacterial skin infections. To make an accurate diagnosis, the physician looks for a pattern of inflammation and signs of lymphatic obstruction, together with the patient's possible exposure to filariasis in an area where filariasis is common. The larvae (microfilariae) can also be found in the blood, but because mosquitos, which spread the disease, are active at night, the larvae are usually only found in the blood between about 10 p.m. and 2 a.m.

Treatment

Either ivermectin, albendazole, or diethylcarbamazine is used to treat a filariasis infection by eliminating the larvae, impairing the adult worms' ability to reproduce, and by actually killing adult worms. Unfortunately, much of the tissue damage may not be reversible. The medication is started at low doses to prevent reactions caused by large numbers of dying parasites.

While effective, the medications can cause severe side effects in up to 70% of patients as a result either of the drug itself or the massive death of parasites in the blood. Diethylcarbamazine, for example, can cause severe allergic reactions and the formation of pus-filled sores (abscesses). These side effects can be controlled using **antihistamines** and anti-inflammatory drugs (**corticosteroids**). Rarely, treatment with diethylcarbamazine in someone with very high levels of parasite infection may lead to a fatal inflammation of the brain (encephalitis). In this case, the fever is followed by headache and confusion, then stupor and **coma** caused when massive numbers of larvae and parasites die. Other common drug reactions include **dizziness**, weakness, and nausea.

Symptoms caused by the death of the parasites include fever, headache, muscle pain, abdominal pain, **nausea and vomiting**, weakness, dizziness, lethargy, and **asthma**. Reactions usually begin within two days of starting treatment and may last between two and four days.

No treatment can reverse elephantiasis. Surgery may be used to remove surplus tissue and provide a way to drain the fluid around the damaged lymphatic vessels. Surgery may also be used to ease massive enlargement of the scrotum. Elephantiasis of the legs can also be helped by elevating the legs and providing support with elastic bandages.

Prognosis

The outlook is good in early or mild cases, especially if the patient can avoid being infected again. The disease is rarely fatal, and with continued WHO medical intervention, even gross elephantiasis is now becoming rare.

Prevention

The best method of preventing filariasis is to avoid repeated bites by the mosquitoes that carry the disease. Some methods of preventing insect bites include the following:

- limit outdoor activities at night, particularly in rural or jungle areas
- wear long sleeves and pants and avoid dark-colored clothing that attracts mosquitoes
- avoid perfumes and colognes
- treat one or two sets of clothing ahead of time with permethrin (Duramon, Permanone).
- wear DEET insect repellent or, especially for children, try citronella or lemon eucalyptus, to repel insects
- if sleeping in an open area or in a room with poor screens, use a bed net to avoid being bitten while asleep
- use air conditioning, the cooler air makes insects less active.

WWW.BOOKBAZ.IR

KEY TERMS

Abscess—An area of inflamed and injured body tissue that fills with pus.

Antibody—A specific protein produced by the immune system in response to a specific foreign protein or particle called an antigen.

Conjunctiva—The mucous membrane that lines the inside of the eyelid and the exposed surface of the eyeball.

Elephantiasis—A condition characterized by the gross enlargement of limbs and/or the genitalia that is also accompanied by a hardening and stretching of the overlying skin. Often a result of an obstruction in the lymphatic system caused by infection with a filarial worm.

Encephalitis—Inflammation of the brain.

Lymphatic system—The circulatory system that drains and circulates fluid containing nutrients, waste products, and immune cells, from between cells, organs, and other tissue spaces.

Microfilariae—The larvae and infective form of filarial worms.

Nematode—Round worms.

Subcutaneous—The area directly beneath the skin.

In addition, filariasis can be controlled in highly infested areas by taking ivermectin preventatively before being bitten. Currently, there is no vaccine available, but scientists are working on a preventative vaccine at this time.

Finasteride

Definition

Finasteride is a drug that belongs to the class of androgen inhibitors, which means that it blocks the production of male sex hormones.

Purpose

Finasteride has two main purposes: the treatment of urinary problems in men caused by benign prostatic hypertrophy (BPH) or enlargement of the prostate gland; and the stimulation of new hair growth in men with male pattern baldness. Finasteride was first approved by the U.S. Food and Drug Administration (FDA) in 1992 under the trade name Proscar as a treatment for BPH. This drug may be used alone or in combination with the drug doxazosin (Cardura) to treat BPH. It received a second FDA approval in December 1997 under the trade name Propecia for the treatment of hair loss in men.

Results of a large clinical trial, the Prostate Cancer Prevention Trial, which were released in 2010, revealed that finasteride (Proscar) reduced the risk for **prostate cancer** by as much as 25% in men (ages 55 and older) enrolled in the trial. In the near future, men with an increasing prostate specific antigen (PSA) level and who are considered by their physicians to be at high risk for the development of prostate cancer may be prescribed finasteride to decrease their risk for developing prostate cancer.

Finasteride works to relieve such symptoms of prostate enlargement as urinary urgency, the need to urinate frequently at night (nocturia), inability to completely empty the bladder, incontinence, or painful urination (dysuria) by blocking the production of DHT. DHT causes the prostate gland to grow and increase pressure on the bladder. As the swollen prostate gradually shrinks, the patient finds it easier to pass urine without discomfort and to empty the bladder completely before going to sleep. Some doctors also prescribe finasteride as pretreatment for prostate surgery, as it lowers the risk of severe bleeding during the operation.

Description

Finasteride is sold in the United States and Canada under the brand names Proscar (indicated for the treatment of BPH) and Propecia (indicated for the treatment of male pattern baldness). Finasteride

KEY TERMS

Alopecia—The medical term for baldness.

Androgens—A group of hormones that produce masculine characteristics.

Chemo preventative—Description of a drug given in order to prevent the development of a specific disease.

Dysuria—Painful or difficult urination.

Incontinence—Inability to control urination or defecation.

Nocturia—Excessive need to urinate at night.

Prostate—A gland in males below the bladder that surrounds the urethra. Enlargement of the prostate may cause problems in urination.

Urgency—A sudden and powerful need to urinate.

inhibits the body's production of an enzyme called 5-alpha-reductase, which is needed to convert testosterone to another androgen called 5-alpha-dihydrotestosterone (DHT). Finasteride is a white powder that can be dissolved in alcohol or chloroform but is very difficult to dissolve in water. Both Proscar and Propecia are manufactured as coated tablets to be taken by mouth.

Recommended dosage

- Proscar: Finasteride for treatment of an enlarged prostate is taken once a day as a 5-mg tablet. The pill may be crushed or broken if the patient finds it hard to swallow.
- Propecia: Finasteride for hair regrowth is taken once a day as a 1-mg tablet. The drug may be taken with or without meals.

Risks

Finasteride should be stored in a dry place and kept at a temperature between 59°F and 86°F (15–30°C). Heat and moisture may cause the drug to lose its potency.

Tablets, especially crushed or broken tablets, should not be touched by a pregnant woman as the drug can be absorbed through the skin. If the woman is carrying a male fetus, the drug can cause abnormalities in the baby's sex organs. The FDA issued a warning in 2003 that men taking finasteride should not donate blood until one month after the final dose of the drug, on the grounds that their blood could contain high enough levels of the medication to cause **birth defects** in a male baby if given to a pregnant woman.

Patients should be advised that finasteride takes several months to reach its full effect—as long as six months for BPH and three months for hair regrowth. In addition, the drug's effects on the body are not permanent; the prostate will start to enlarge again or the hair growth will be lost if the patient stops taking the drug.

Proscar can affect the results of a prostate-specific antigen (PSA) test for cancer of the prostate.

Finasteride should be used cautiously by men with liver disorders.

Finasteride is not indicated for the treatment of hair loss in women in the United States.

Reported side effects from using finasteride include:

- impotence or loss of interest in sex
- lumps or pain in the breast or a discharge from the nipple
- skin rash, itching, or hives
- swelling of the lips or face
- a smaller quantity of ejaculate during intercourse (which does not affect fertility)
- headaches, dizziness, or diarrhea
- pain in the testicles

These side effects are more common with the 5-mg dose, but usually disappear when the drug is discontinued.

Finasteride has not been reported to cause significant interactions with other medications.

Fingernail removal *see* **Nail removal**

Fingertip injuries

Definition

Fingertip **trauma** covers cuts, accumulation of blood (hematoma), bone breakage, or **amputation** in the fingertip.

Description

The fingertips are specialized areas of the hand with highly developed sensory and manipulative functions. Large sensory and motor areas located in the brain regulate the precise and delicate functions of fingertips. The fingertip is the site where extensor and flexor tendons insert. Fingertip injuries are extremely common since the hands hold a wide array of objects. In 2001, approximately 10% of all accidents in the United States that were referred for emergency room consults involved the hand. Hand injuries are frequently the result of job injuries and account for 11–14% of on-the-job injuries and 6% of compensation paid injuries. Injury to the nail bed occurs in approximately 15–24% of fingertip injuries.

Fingertip injuries can result in amputation or tissue loss. The injury is assessed whether the bone and underlying tissue are intact and the size of the wound area. The pulp is the area of skin opposite the fingernail and is usually very vulnerable to injury. Pulp injuries commonly occur in persons who use or are in close contact with fast moving mechanical devices. These injuries can crush, cut, and puncture. The fingertips can also be injured by common crushing accidents. This could cause the development of a subungal hematoma (an accumulation of blood under the nail).

At the base of the distal phalanx (the first circular skin fold from the tip) injuries can occur that can fracture the underlying bone in the area. Quite commonly a hammer, closing a door, or sport accidents usually cause these injuries. These **fractures** can be simple, requiring little treatment or more complicated involving the joint. The accident may involve the point of insertion of a tendon. Usually this occurs when the terminal joint is being forced to flex while held straight. This motion typically occurs when tucking in sheets during bed making, a common cause of tendon injury. This injury causes a loss of extension (straightening the finger) ability.

Causes and symptoms

Accidental amputations will usually result in profuse bleeding and tissue loss. Injuries to the pulp can occur as from fast-moving mechanical instruments, such as drills. These injuries may puncture the pulp. Injuries such as a subungal hematoma are caused by a crushing type injury. Fractures typically occur as the result of crushing injuries or tendon avulsion. These crushing injuries are frequently caused during sport injury and can be treated by simple interventions such as **immobilization** or more complex procedures if tendons are affected (the trauma is then treated as a tendon injury). Fractures can cause **pain** and, depending on the extent of swelling, there may be some restriction of movement. Tendon injuries can be caused when the terminal joint is exposed to force flexing motion (moving the finger toward the palm) while held straight.

Diagnosis

The attending clinician should evaluate the injury in a careful and systematic manner. The appearance of the hand can provide valuable information concerning presence of fractures, vascular status, and tendon involvement. Bones and joints should be evaluated for motion and tenderness. Nerves should be examined for sensory (feeling sensations) and motor (movement) functioning. Amputations usually profusely bleed and there is tissue loss. The wound is treated based on loss of tissue, bone, and wound area. Injuries to the pulp can be obvious during inspection. Subungal hematoma usually present a purplish-black discoloration under the nail. This is due to a hematoma underneath the nail. Radiographs may be required to assess the alignment of fractures or detect foreign bodies. Patients usually suffer from pain since injuries to the fingertip bone are usually painful and

KEY TERMS

Distal—Movement away from the origin.

Flex—To bend.

Laceration—A cut in the skin

Phalanx—A bone of the fingers or toes.

Tendon—A structure that connects a skeletal muscle to bone.

movement may be partially restricted due to swelling of the affected area. Tendon injuries usually result in the loss of ability to straighten or bend the finger.

Treatment

Amputation in which bone and underlying tissue are intact and the wound area is 1 cm or less, should be cleaned and treated with a dressing. With these types of **wounds**, healthy tissue will usually grow and replace the injured area. Larger wounds may require surgical intervention. Puncture wounds should be cleaned and left open to heal. Patients typically receive **antibiotics** to prevent infection. A procedure called trephining treats subungal hematomas. This procedure is usually done with a straight cutting needle positioned over the nail. The clinician spins the needle with forefinger and thumb until a hole is made through the nail.

Patients who have extensive crush injuries or subungal hematomas involving laceration to skin folds or nail damage should have the nail removed to examine the underlying tissue (called the matrix). Patients who have a closed subungal hematoma with an intact nail and no other damage (no nail disruption or laceration) are treated conservatively. If the fracture is located two-thirds below the fingertip, immobilization using a splint may be needed. Conservative treatment is recommended for crush injuries that fracture the terminal phalanx if a subungal hematoma is not present. Severe fractures near the fist circular skin crease may require surgical correction to prevent irregularity of the joint surface, which can cause difficulty with movement. Injury to a flexor tendon usually requires surgical repair. If this is not possible, the finger and wrist should be placed in a splint with specific positioning to prevent further damage.

Prognosis

Prognosis depends on the extent of traumatic damage to the affected area. Nail lacerations that are not treated may cause nail deformities. When amputation is accompanied with loss of two-thirds of the nail, half of the fingers develop beaking, or a curved nail. Aftercare and follow up are important components of treatment. The patient is advised to keep the hand elevated, check with a clinician two days after treatment, and to splint fractures for two weeks in the extended position. Usually a nail takes about 100 days to fully grow. Healing for an amputation takes about 21-27 days. This markedly decreases in elderly patients, primarily due to a compromised circulation normally part of advancing age.

First aid

Definition

First aid is the treatment of minor injuries or conditions, or immediate care or treatment for a medical emergency that is administered while awaiting professional help.

Purpose

First aid ranges from cleaning and bandaging a minor scrape to saving a life with cardiopulmonary resuscitation (CPR). It is often required to stop bleeding or to stabilize and protect an ill or injured person until they can get to a hospital or emergency help arrives on the scene. First aid may be used to treat:

- cuts, scrapes, and scratches
- nosebleeds
- severe bleeding
- heat exhaustion and heatstroke
- frostnip and frostbite
- burns
- poisoning
- choking
- a foreign object in the eye or nose

- injured or broken bones
- head or spinal injuries
- seizures
- shock
- unconsciousness
- respiratory or heart failure

Demographics

Every year millions of children require first aid for minor injuries, serious accidents, or life-threatening emergencies. For this reason, every home, automobile, daycare, and school should be equipped with a well-stocked first-aid kit and every parent, caregiver, and teacher should be trained in first aid and CPR.

Description

First aid varies depending on the injury and its severity. For instance, first aid for a minor scrape, cut, or puncture wound may include:

- using sterile gauze, tissue, or a clean, soft cloth to apply gentle, firm pressure to stop bleeding
- cleaning with cool running water or soaking the wound
- using a soft cloth and gentle soap to clean around the injury
- using a soft, damp cloth or tweezers cleaned with rubbing alcohol to remove dirt or debris
- applying antibiotic ointment
- covering with butterfly tape, adhesive strips, or sterile gauze and adhesive tape, if the injury is in an area that could get dirty or rubbed by clothing
- changing bandages daily

First aid for severe bleeding, on the other hand, may include:

- lying down and covering the injured person to prevent loss of body heat
- elevating the legs, if possible, to increase blood flow to the brain and prevent fainting; or elevating the injured area above the level of the heart to slow bleeding
- applying firm, gentle pressure to the wound for at least 20 minutes
- adding more gauze or cloth, if needed, without removing the lower layers
- applying pressure to a main artery leading to the injured area
- tightly wrapping the wound with a bandage or clean cloth and tape
- immobilizing the injured part and leaving bandages in place once the bleeding has stopped

Some first-aid measures for a sampling of other injuries and conditions follows.

Heat exhaustion or heatstroke

- Placing the patient in a cool, shady spot, with unnecessary clothing removed.
- Having the patient drink plenty of water or other fluids.
- Bathing or spraying the patient with cool water, and allowing water to evaporate.

Frostnip or frostbite

- Dressing the patient in dry clothing, placing him or her in a warm environment, and having the patient drink warm fluids.

- If emergency help is not immediately available for frostbite, immersing the frozen parts in warm water (100°F, 38°C) or treating them with warm compresses for 30 minutes.
- If warm water is unavailable, gently wrapping the patient in blankets.

Burns

- Gently removing clothing from around the burn, unless it is stuck to the skin.
- Soaking first-degree burns in cool water for at least five minutes, and loosely wrapping with a dry gauze bandage or a clean soft towel or sheet.
- Soaking second-degree burns in cool water for 15 minutes, and covering with a dry, nonstick dressing that is changed daily.
- Covering third-degree burns with a cool, wet, sterile bandage or clean cloth, without first soaking the burn, and if possible, raising the burned area above the level of the heart until medical assistance is available.
- Covering electrical burns with gauze without rinsing.
- For chemical burns, removing any contaminated clothing or jewelry, and brushing any dry chemical from the skin; gently rinsing the burn with cool, running water for at least 20 minutes; loosely wrapping with a dry, sterile, dressing or gauze or a clean cloth; and rewashing if the pain worsens.

Additional first-aid measures are available for many other injuries and conditions.

Benefits

First aid can save lives. It can also prevent injuries from worsening or becoming infected and can speed healing.

Precautions

Serious injuries or emergency medical situations require summoning emergency responders, usually by calling 911, or rushing the patient to a hospital emergency room or other critical care facility. Precautions for administering first aid depend on the type of injury. Some of the most important precautions include never:

- moving a person if there is any possibility of spinal injury
- applying a tourniquet to stop bleeding
- attempting to remove a deeply imbedded object
- attempting to replace organs
- using direct heat on frostbite or rubbing frostbitten skin
- thawing frostbitten skin if there is a risk of refreezing
- breaking burn blisters or applying ice or any ointment or lotion to burns except under a doctor's direction
- giving anything to someone who may have ingested a toxin and never inducing vomiting, unless directed by the poison control center
- attempting to remove an object embedded in the eyeball or rubbing the eyes
- probing the nose for an object that is not visible and easily grasped
- washing or moving bone injuries
- restraining movement or putting anything in the mouth of a person having a seizure
- attempting to awake an unconscious person by shaking, slapping, or using cold water
- putting a pillow under an unconscious person's head, as this can block an airway
- providing care to a bleeding patient without first donning gloves or other protective gear, as necessary

Preparation

An individual can prepare for first-aid by taking first-aid classes, learning CPR and renewing CPR certification at least every two years, and by learning to use an automatic external defibrillator (AED). Anyone can learn basic first aid, including children. First-aid guidelines are updated over time, so it is important to stay abreast of current recommendations. For instance, the American Heart Association revised its guidelines for cardiopulmonary respiration in 2010.

Caregivers, including babysitters and others who work with children and the elderly, should receive training in first aid and CPR. Every home and automobile should have a well-stocked first-aid kit. First-aid kits are often designed for specific activities, such as hiking, camping, or boating, and should include items geared toward those activities. For example, a camping kit might include ointment for mosquito bites. The contents of a first-aid kit should be checked regularly for missing items and expired medicines. Any medicines should be in their original containers, and marked with dosage and instructions.

A typical, general-purpose, first-aid kit may contain:

- emergency and physician phone numbers
- a list of allergies and medications for all family members

WWW.BOOKBAZ.IR

- medical consent and medical history forms, as necessary
- a first-aid manual
- a waterproof flashlight and batteries
- duct tape
- scissors, tweezers, needles, and safety pins
- a non-mercury, non-glass, oral thermometer
- sterile, disposable gloves
- eye goggles or eye shield
- a breathing barrier or mouthpiece for CPR
- a Mylar emergency blanket
- aluminum finger splints
- a tooth-saver kit
- a bulb suction device for flushing out wounds
- instant cold packs
- assorted adhesive bandages, gauze pads, roller gauze, and compress dressings
- adhesive cloth tape
- an elastic bandage
- sterile cotton balls and cotton-tipped swabs
- plastic bags for waste
- soap, hand sanitizer, and alcohol wipes
- antiseptic solution or wipes
- sterile eyewash or saline solution
- petroleum jelly or other lubricant
- aloe vera gel
- calamine lotion
- antibiotic ointment or cream
- hydrocortisone ointment or cream
- a medicine cup or spoon and oral medicine syringe
- aspirin, acetaminophen, and ibuprofen
- anti-diarrhea medication
- antihistamines
- decongestant
- cough suppressant
- antacid
- laxatives
- sunscreen
- prescription medications that do not need refrigeration
- prescribed medical supplies, as necessary

Aftercare

Aftercare varies based on the injury or condition being treated, For most small cuts, scrapes, and abrasions, for instance, bandages should be changed daily or whenever they become wet or dirty and antibiotic ointment applied as necessary, but they will typically heal without any special care. For a bone injury, on the other hand, the area should be elevated and ice packs or cold compresses applied every few hours for 20-minute periods.

KEY TERMS

Aloe vera—An extract from the plant *Aloe barbadensis* that is used in skin creams and for treating burns.

Automatic external defibrillator (AED)—An electronic device for restoring regular heart rhythm.

Cardiopulmonary resuscitation (CPR)—A procedure for restoring normal breathing following cardiac arrest. It includes clearing the air passages, mouth-to-mouth artificial respiration, and heart massage by exerting pressure on the chest.

Shock—Severe depression of vital physiological processes, characterized by paleness, a rapid but weak pulse, rapid and shallow breathing, and low blood pressure; typically caused by injury, severe bleeding, or burns.

Risks

An individual should be cautious about providing first-aid and must assess the situation before getting involved. If the situation is dangerous, such as the scene of an accident where hazards exist, the individual should contact emergency personnel by dialing 911. When coming in contact with blood or other bodily fluids, there may be a risk of infection with HIV, hepatitis virus, or some other infectious agent. Wearing latex gloves can help prevent disease transmission. A mouth-to-mouth barrier device is recommended when giving rescue breaths, but first-aid providers should know that even this may not protect against contracting an infection.

REVISED BY LESLIE MERTZ, PhD

Fish and shellfish poisoning

Definition

Fish and shellfish **poisoning** is a common but often unrecognized group of illnesses related to food. Three of these illnesses include ciguatera, scombroid, and paralytic shellfish poisoning.

Ciguatera

Definition

Ciguatera (from the Spanish word for a poisonous snail) is a food-related illness that causes abdominal and neurological symptoms.

Causes and symptoms

Ciguatera is caused by eating fish that have a toxin called ciguatoxin. Scientists believe this toxin is acquired by the fish through the food chain, and is originally produced by small algae microorganisms (dinoflagellates). The fish most likely contaminated with ciguatoxin are those that feed close to tropical reefs, including red snapper, grouper, and barracuda. Larger fish are more likely to contain the toxin. Although not as common in the United States,

WWW.BOOKBAZ.IR

ciguatera is commonly diagnosed on many of the islands in the Pacific Ocean.

Illness from ciguatera can occur in just a few minutes to about 30 hours after eating. Most cases occur one to six hours after eating the contaminated fish. Initial symptoms are abdominal cramps, nausea, **vomiting**, or watery **diarrhea**. The most characteristic symptoms of the illness are those involving the nervous system. These include **numbness and tingling** around the lips, tongue, and mouth; **itching**; **dry mouth**; metallic taste in the mouth; and blurry vision. In more prominent cases, patients may complain of temporary blindness, a slow pulse, and a feeling that their teeth are loose. Patients may also have the strange symptom of reversal of hot and cold sensations on the skin, where cold things feel very hot or painful to the touch. In very severe cases, patients may experience difficulties in breathing or low blood pressure.

Diagnosis

Ciguatera diagnosis is based on the typical combination of symptoms after eating fish. There are no readily available blood or urine tests to detect the poisoning, but some researchers have developed a test for the toxin left on any remaining fish. A person does not have to be in a tropical area to get ciguatera. Fish can be caught from one of these distant areas, and can then be shipped and eaten locally. It is important to report suspected cases to local **public health** officials because more cases may occur from other contaminated fish.

Treatment

The treatment for this illness is general. Patients are given fluids (by mouth or through a vein) and medications to decrease the itching or to treat vomiting and/or diarrhea. The neurological symptoms can cause discomfort and treatment with amitriptyline (a medicine that has been used for depression) may be useful. Other medications may also be given.

Prognosis

Although death can occur, almost all patients diagnosed with ciguatera will recover. Recovery, however, can be slow and some symptoms can last for weeks or even months. Symptoms can also be aggravated by other illnesses or alcohol.

Prevention

Knowing the kinds of fish linked to ciguatera can help a person avoid eating high-risk fish. However, more than 400 different kinds of fish have been linked to the disease, even salmon. A particular fish in a given area may be more likely to cause ciguatera than other fish. For example, red snapper is most often the source of ciguatera in the Pacific, while barracuda is more likely to contain the toxin in Florida. This is why it is illegal to sell barracuda in Florida for human consumption. Cooking the fish does not prevent ciguatera.

Scombroid

Definition

Scombroid is a fish-associated illness caused by eating improperly handled fish. Fish linked to this disease are usually in the Scombridae family, which includes yellowfin tuna, skipjack, bonito, and mackerel.

Causes and symptoms

Scombroid occurs after eating fish that has not been properly refrigerated after capture. Unlike ciguatera, the toxins linked with scombroid are not contracted by the fish from its surroundings. Bacteria that are normally found in fish act directly on a chemical (called histidine) in the flesh of fish that are not properly cooled when stored. This interaction produces histamine and other chemicals that cause the illness when the fish is eaten.

Symptoms of scombroid occur quickly after eating the fish, as soon as 10 minutes. Since histamine is released by certain cells in the body during an allergic reaction, scombroid can be confused with a fish allergy. Scombroid causes flushing of the face, sweating, a burning feeling in the mouth or throat, vomiting, diarrhea, and headaches. A rash that looks like a **sunburn** may occur, and a small number of patients have **hives**. Some patients have a metallic or peppery taste in their mouths. In more severe cases, rapid pulse, blurred vision, and difficulty breathing can occur. Symptoms usually last about four hours.

Diagnosis

Like ciguatera, scombroid poisoning is diagnosed based on typical symptoms occurring after eating fish. There are usually no available tests for the patient. Experimentally, however, elevated levels of histamine-related products have been found in the urine. It may be possible for public health officials to test any remaining fish flesh for histamine levels. Improperly refrigerated fish caught in both temperate and tropical waters have been linked to the illness. An outbreak of

KEY TERMS

Algae—Plants that have one cell.

Histamine—A chemical found naturally in the body that produces inflammation and increases blood flow; the uncomfortable symptoms of an allergy attack or an allergic reaction are generally caused by the release of histamine.

Toxin—A poisonous substance usually produced by a living thing.

similar cases may be helpful in correctly diagnosing the problem.

Treatment

The treatment for scombroid is usually general. **Antihistamines** like diphenhydramine (Benadryl) may shorten the duration of the illness, but the illness will go away on its own. Some doctors have found that cimetidine (Tagamet) given through a vein may be helpful as well. In rare, more severe cases, epinephrine (adrenaline) may be used.

Prognosis

Although sometimes dramatic and alarming symptoms can occur, scombroid is usually not serious. The patient should be reassured that scombroid is not a fish allergy.

Prevention

Adequate storage of the target fish will always prevent scombroid. Since the fish does not appear spoiled or smell bad, the consumer cannot detect the risk of the illness before eating the fish. Cooking the fish does not prevent scombroid. Suspected cases should be reported to public health officials.

Paralytic shellfish poisoning

Definition

Paralytic shellfish poisoning (PSP) is a nervous system disease caused by eating cooked or raw shellfish that contain environmental toxins. These toxins are produced by a group of algae (dinoflagellates). It is unclear whether these toxins are related to the "blooming" of the algae, also called red tide because the algae can turn the water reddish brown. PSP occurs mostly in May through November.

Causes and symptoms

PSP develops usually within minutes after eating a contaminated shellfish, most commonly a mussel, clam, or oyster. Symptoms include **headache**, a floating feeling, **dizziness**, lack of coordination, and tingling of the mouth, arms, or legs. Muscle weakness causing difficulty swallowing or speaking may occur. Abdominal symptoms such as nausea, vomiting, and diarrhea can also occur. Unlike ciguatera and scombroid, PSP may have a much more serious outcome. PSP may cause difficulty breathing related to weakness or **paralysis** of the breathing muscle. The symptoms may last for six to 12 hours, but a patient may continue to feel weak for a week or more.

Diagnosis

PSP diagnosis is based on symptoms after eating shellfish, even if the shellfish are adequately cooked. No blood or urine test is available to diagnose the illness, but tests in mice to detect the toxin from the eaten fish can be done by public health officials.

Treatment

The treatment of PSP is mostly supportive. If early symptoms are recognized, the doctor will try to flush the toxin from the gastrointestinal tract with medications that create diarrhea. Vomiting may be induced if the patient has no signs of weakness. In cases where the muscles of breathing are weakened, the patient may be placed on a respirator until the weakness goes away. However, this measure is not usually needed. Likewise, the use of a machine to clean the blood (dialysis) has been used in severe cases.

Prognosis

The prognosis for PSP is quite good, especially if the patient has passed the initial 12 hours of illness without needing breathing support. Most deaths occur during this period if breathing help is not available.

Prevention

Measures to control PSP require detecting rising numbers of algae in coastal waters by periodic microscopic examination. By law, shellfish beds are closed when levels of the toxin-producing organisms are above acceptable standards. Cooking the shellfish does not prevent this disease. Suspected cases should be reported to public health officials.

Fistula

Definition

A fistula is a permanent abnormal passageway between two organs in the body or between an organ and the exterior of the body.

Description

Fistulas can arise in any part of the body, but they are most common in the digestive tract. Fistulas usually develop as a result of damaged tissues contacting with each other and uniting during healing. They can also develop between blood vessels and in the urinary, reproductive, and lymphatic systems.

Fistulas are categorized by the number of openings they have and whether they connect two internal organs or open through the skin. There are four common types:

- Blind fistulas are open on one end only.
- Complete fistulas have one internal opening and one opening on the skin.
- Horseshoe fistulas are complex fistulas with more than one opening on the exterior of the body.
- Incomplete fistulas are tubes of skin that are open on the outside but closed on the inside and do not connect to any internal structure.

Fistulas of the digestive tract

Anal and rectal fistulas develop in the wall of the anus or rectum. They connect the interior of the body to one or several openings in the skin. Anal and rectal fistulas almost always begin as an inflammation in an anal gland. The inflammation then moves into muscle tissue and develops into an **abscess**. In about half of all cases, the abscess develops into a fistula, degrading the muscle until an opening in the skin is created. About nine people of every 100,000 develop anal fistulas, with men almost twice more likely to develop the condition than women. Although they may develop at any age, the average age for the development of anal fistulas is 38.

Intestinal fistulas can develop in both the large and small intestine. They are commonly associated with diseases such as inflammatory bowel disease (IBD) and Crohn's disease.

Tracheoesophageal fistulas (TEF) are usually **birth defects**. They are categorized by where the fistula is located and how the esophagus and trachea are connected, but all are life-threatening and require prompt surgery to repair. The abnormal connection of the windpipe, or trachea, to the esophagus allows air to enter the digestive system and makes it possible to breathe food into the lungs (aspiration). In many cases, the esophagus is also incomplete, causing immediate feeding problems.

Fistulas of the urinary and reproductive tract

The most common type of fistula involving these systems is a vesicovaginal fistula, in which the woman's vagina is connected to the urinary bladder. This causes leakage of urine from the vagina and results in frequent vaginal and bladder infections. Fistulas may also develop between the vagina and the large intestine (a enterovaginal fistula) so that feces leaks from the vagina. Although these types of fistulas are uncommon in the developed world, they are common in poor developing countries and result from long, difficult labor and **childbirth**, especially in very young girls. As a result, they are sometimes referred to as obstetric fistulas. If left unrepaired, obstetric fistulas cause women to constantly leak urine and feces. As expected, they may suffer severe social issues, extreme hardship, and psychological **trauma**.

Fistulas of the circulatory system

Arteriovenous fistulas (AVF) can develop between an artery and a vein in any part of the body. These fistulas vary in size, length, and frequency. Arteries contain blood carrying oxygen to all parts of the body, whereas veins carry blood that has given up its oxygen back to the lungs. Connections between arteries and veins cause changes in blood pressure that result in abnormal development of the walls of the arteries and abnormal blood flow. Arteriovenous fistulas that are present at birth are sometimes referred to as **arteriovenous malformations** (AVMs). Many arteriovenous fistulas are present, but not evident at birth, and become obvious only after trauma. AVFs can also be acquired from penetrating trauma.

Demographics

Fistulas can occur at any age or can be present at birth (congenital). Some are life-threatening, others cause discomfort, while still others are benign and go undetected or cause few symptoms. Diabetics, individuals with compromised immune systems (**AIDS**, cancer), and individuals with certain gastrointestinal diseases (Crohn's disease, inflammatory bowel disease) are at increased risk of developing fistulas. There are several types of tracheoesophageal fistulas (TEF). TEFs occur in about one of every 1,500–3,000 births. Some experts suggest that in parts of Africa, as many as three to four women develop obstetric fistulas for every 1,000 births. Others estimate that as many as 2 million women worldwide are living with unrepaired obstetric fistulas.

Causes and symptoms

The causes and symptoms of fistulas vary depending on their location. Anal and rectal fistulas are usually caused by an abscess. Symptoms include constant throbbing **pain** and swelling in the rectal area. Pus is sometimes visible draining from the fistula opening on the skin. Many individuals have a **fever** resulting from the infection causing the abscess.

Vaginal fistulas are caused by infection and trauma to the tissue during childbirth. They are easily detected, because the woman smells unpleasant and leaks urine or feces through her vagina. Rarely these fistulas may develop as a complication of **hysterectomy**.

Tracheoesophageal fistulas are the result of errors in the development of the fetus. They are evident at birth, because the infant is unable to swallow or eat normally and are considered a medical emergency that requires surgery if the infant is to survive.

Arteriovenous fistulas (AVFs) are most often congenital defects. Symptoms vary depending on the size and location of the fistula. Often the skin is bright pink or dark red in the area of the fistula. Individuals may complain of pain. The pain is a result of some tissues not receiving enough oxygen because of abnormal blood flow.

Doctors sometimes create fistulas intentionally. An AVF may be created in preparation for hemodialysis. Joining an artery to a vein causes the vein to enlarge greatly, providing a site for repeated puncture. For some patients requiring long-term placement of a feeding tube, the doctor may create an opening between the skin of the abdomen and the inside of the stomach. A **colostomy** or nephrostomy is a fistula that allows the colon or kidney, respectively, to drain to the outside in cases of blockage.

KEY TERMS

Abscess—A collection of pus surrounded by inflamed, infected tissue.

Hysterectomy—Surgery to remove a woman's uterus or womb.

Lymphatic system—The part of the circulatory system that carries lymph, a clear fluid that is involved in immune system response.

Diagnosis

Tests used to determine the presence of a fistula vary with the location of the fistula. When there is an opening to the outside, the physician may be able to see the fistula and probe it. Various imaging studies such as x rays, CT scans, barium **enemas**, **endoscopy**, and ultrasonography are used to locate less visible fistulas. Patients are often given a fistulogram (x-ray examination) to see if there are any blockages or narrowing in the fistula.

Treatment

Anal and rectal fistulas are treated by draining the pus the infected area. The individual also is usually given **antibiotics** to help prevent recurrence of the abscess. If this fails to heal the fistula, surgery may be necessary.

Intestinal fistulas are treated first by reducing the inflammation in the intestine and then, if necessary, with surgery. Treatment varies considerably depending on the degree of severity of symptoms the fistula causes. TEFs are always treated with surgery. Obstetric fistulas must also be repaired with surgery. The treatment of arteriovenous fistulas depends on the size and location of the fistula and usually includes surgery. A fistuloplasty is a nonsurgical procedure that is commonly used to open up blocked or narrowed vessels in an intentional AV fistula used for dialysis; this procedure is performed to improve the function of the fistula.

Alternatives

No effective alternative treatments for fistulas are known.

WWW.BOOKBAZ.IR

Prognosis

The outcome of fistulas depends on the type and cause of the condition. Surgical repair of obstetric fistulas is almost always successful. Unfortunately, many women in developing countries do not have access to this type of surgery. Treatment of anal and rectal fistulas is almost always successful, although fistulas may recur in up to 18% of individuals. The outcome of surgery on TEFs is highly variable, especially since infants born with this condition often have other developmental abnormalities that may affect the outcome of fistula repair. The degree of successful repair of arteriovenous fistulas depends on their size and location. Uncontrolled bleeding is the most common complication of surgery to repair AVFs.

Fistulas that are intentionally created must be handled carefully and maintained according to the doctor's instructions in order prevent bleeding, clotting, infection, leakage, premature closure, or other problems.

Prevention

Obstetric fistulas are the only preventable fistulas. These can be prevented with good prenatal and childbirth care and by avoiding **pregnancy** in very young girls. Although anal and rectal fistulas are not preventable, their damage can be minimized by prompt drainage and treatment.

REVISED BY KARL FINLEY

Flea-borne disease

Definition

Flea-borne diseases are zoonoses (diseases transmitted from animals to humans) carried by several species of fleas that live in the fur of wild rodents (rats, mice, prairie dogs, and squirrels); other wild animals (skunks, coyotes, raccoons, rabbits); and domestic pets (cats and dogs). Fleas are vectors of several bacterial diseases that affect humans in the United States; they do not themselves become ill from the disease bacteria but convey them to humans (or other animals) through their saliva when they bite the human host after feeding on blood from an infected animal.

There are three major flea-borne diseases that affect people living in the continental United States:

• Plague, caused by the bacterium *Yersinia pestis*.

Flea bites visible on a journalist's body while on assignment in Afghanistan. *(AP Images/David Guttenfelder)*

- Murine typhus (also called endemic typhus), caused by the bacterium *Rickettsia typhi*. It should not be confused with epidemic typhus, which is caused by a different bacterium carried by body lice. The English word *murine* is derived from the Latin word for mouse.
- Cat-scratch disease, caused by the proteobacterium *Bartonella henselae*. Humans acquire the disease when scratched or bitten by an infected cat; however, fleas are the vectors that transmit *B. henselae* from one cat to another.

A fourth **flea-borne disease**, flea-borne spotted **fever**, is caused by the bacterium *Rickettsia felis*. It is considered an emerging **infectious disease** (EID) because only four cases have been reported in North America since 1991: one in Texas and three in Mexico. The remainder of this entry will focus on the three most common flea-borne diseases in the United States.

Description

Flea-borne diseases are endemic in North America, which means that they remain at a low level within the general population, neither disappearing entirely nor increasing at an exponential rate, as is the case in an epidemic. Of the estimated 2,500 species of fleas in the world, about 325 species are found in the continental United States. Ninety-four percent of these species are ectoparasites on mammals, and 6% are found on birds. The most important species of fleas from the standpoint of **public health** in North America are the so-called cat flea, *Ctenocephalides felis*, which is the vector of murine **typhus**, **cat-scratch disease**, and flea-borne spotted fever; and the Oriental rat flea, *Xenopsylla cheopis*, the vector of bubonic **plague**.

Xenopsylla cheopis favors dry areas like the deserts of Asia, Egypt, and sub-Saharan Africa, whereas *Ctenocephalides felis* is one of the most widespread species on flea worldwide, found in the temperate zones and rainy climates as well as in deserts. The adult Oriental rat flea is about 2.5 mm long and the cat flea is slightly smaller, about 2 mm long. Fleas are wingless insects, but have long legs that enable them to leap easily from one host to another. The flea's mouth has two functions: to suck blood from the host and to inject saliva into the bite; it is this second function that makes fleas vectors of bacterial disease.

Risk factors

Risk factors for flea-borne diseases include:

- Living in the southwestern United States, California, far western Nevada, southern Oregon, or other arid areas in which plague and murine typhus are endemic.
- Traveling to parts of the world in which murine typhus is endemic, or visiting port cities with large rat populations.
- Occupational exposure to wild rodents, domestic pets, or other animals likely to harbor fleas; these occupations include farming, forestry, field biology, veterinary medicine, park management, archaeology, and epidemiology. Recreational hikers and hunters are also at risk.
- Keeping domestic pets that are allowed to roam freely outdoors.
- Having heavy brush or trees near the house that attract wild rodents, coyotes, and other animals likely to harbor fleas.
- Having a weakened immune system.

Demographics

All four flea-borne diseases are rare in North America as of 2014. About 10 to 15 cases of plague occur each year in North America, almost all of them in the American Southwest or southwestern Canada. The last major outbreak of plague in the United States occurred in Los Angeles, California, between 1924 and 1925.

Between 20 and 80 cases of murine typhus are reported per year, the vast majority in Texas, although cases have also been reported in Hawaii and California. It is thought, however, that the disease is likely underdiagnosed because its symptoms are easily confused with those of epidemic typhus.

Cat-scratch disease affects about 1 in every 10,000 persons per year in North America. It is most common in parts of the United States with warmer than average temperatures and higher humidity (Hawaii, the Pacific Northwest, the southeastern states, and coastal California), and 70–90% of cases occur in the fall and winter months. As has been noted, only four cases of flea-borne spotted fever have been reported in North America since 1991.

Travelers should note, however, that flea-borne diseases are more common elsewhere in the world. Plague is found in arid regions of the Africa, Asia, and South America, with about 3,000 cases reported each year worldwide. Murine typhus is widespread in the tropics, particularly in port cities and coastal areas with large rodent populations. These include the countries surrounding the Mediterranean Sea as well as Asia and Africa. Cases of flea-borne spotted

WWW.BOOKBAZ.IR

fever have been reported in southern Europe, Thailand, South America, and Australia.

Causes and symptoms

The cause of most flea-borne diseases is transmission of the specific bacterium to humans through the bite of an infected flea that has fed on blood from an infected rodent or other mammal. People can also be infected with the plague bacterium by handling an animal that has died of plague. Plague can also take a pneumonic form, in which direct human-to-human transmission is possible through airborne droplets containing the plague bacterium produced by coughing. The bacterium that causes cat-scratch fever is transmitted to humans through the scratch or bite of an infected cat or kitten rather than directly by fleas; the fleas, however, transmit the disease from one cat to another. Infected cats cannot transmit the disease directly to uninfected cats.

Plague can appear in three forms, with the following symptoms:

- Bubonic plague: high fever, headache, and chills with painful, swollen lymph nodes, often in the groin area that appear between two and six days after being bitten by a flea. These swellings, or buboes, are what give the disease its classic name. The bacteria multiply rapidly in the lymph nodes closest to the initial flea bite. If untreated, bubonic plague may progress to septicemic plague.
- Septicemic plague: fever, chills, extreme weakness, abdominal pain, shock, and possibly bleeding into the skin and other organs when the plague bacterium enters the bloodstream and infects the internal organs. Fingers, toes, the nose, and other areas of skin may turn black and die.
- Pneumonic plague: fever, headache, weakness, and pneumonia with difficult breathing, chest pain, cough, and bloody mucus. This form of plague may develop from untreated bubonic or pneumonic plague that spreads to the lungs, or may be transmitted directly from person to person by droplet infection. Cats can also develop pneumonic plague, and cases of direct cat-to-human transmission of plague have been reported.

Murine typhus has the following symptoms, which are similar to those of epidemic typhus but much less severe:

- Headache, joint and muscle pains, backache, nausea, and vomiting, appearing about 12 days after being bitten by an infected flea.
- A spotted rash that appears on the trunk and may spread to the arms and legs.
- Fatigue.

Cat-scratch fever has the following symptoms:

- A lesion that develops at the site of the bite or scratch (most often from a kitten rather than an adult cat).
- Swelling of one or more lymph nodes close to the initial lesion between one and two weeks after the initial scratch or bite.
- About 5–10% of patients develop inflammation of the conjunctivae (the tissue that lines the eyelids) with a concurrent swelling of the lymph node near the ear. They may also develop inflammation of the optic nerve.
- Patients with weakened immune systems may develop systemic disease, which may manifest as arthritis, pneumonia, osteomyelitis, or encephalitis.
- Cats or kittens infected with *B. henselae* do not develop any symptoms and will not appear sick.

Diagnosis

The diagnosis of a flea-borne disease begins with the patient's history, particularly recent exposure to fleas through the patient's occupation or travel. In some cases the patient will remember being bitten by a flea, particularly if he or she had an allergic reaction to the bite. In the case of cat-scratch fever, the patient will usually remember being bitten or scratched by a cat. As noted earlier, murine typhus is difficult to diagnose because its symptoms resemble those of epidemic typhus.

Testing of the patient's blood serum by immunofluorescence analysis (IFA) or enzyme-linked immunosorbent assay (ELISA) can be used to diagnose cat-scratch fever, murine typhus, and plague. Plague can also be diagnosed through examination of sputum, fluid drawn from a bubo, cerebrospinal fluid, or by culturing the organism.

Treatment

All four flea-borne diseases can be treated with **antibiotics**, although cat-scratch fever will resolve by itself in a few weeks in patients with normal immune systems.

- Plague: Plague is a notifiable disease, which means that the CDC and local public health authorities must be notified when a patient is diagnosed with plague. In addition to antibiotic therapy, persons with plague are isolated for 48 to 72 hours or until a sputum culture shows that pneumonia can be ruled out. The patient is given a seven-day course of oral doxycycline

and ciprofloxacin, with chloramphenicol as an alternative; patients with advanced plague require a 10-day course of antibiotics and may need to be placed on a ventilator and given intravenous fluids. The FDA has also approved levofloxacin for the treatment of plague.

- Murine typhus: murine typhus is treated with a 48–72-hour course of antibiotics, most often doxycycline or chloramphenicol, although rifampin is also used.
- Cat-scratch fever: A three to six week course of erythromycin, doxycycline, or azithromycin.

Prognosis

The prognosis of cat-scratch fever and murine typhus is excellent for most patients. As noted above, cat-scratch fever often resolves without treatment and requires hospitalization only for severely immunocompromised persons. Death from cat-scratch fever is extremely unusual. Untreated murine typhus may require hospitalization, but the mortality rate in the United States is only about 2%. Both cat-scratch fever and murine typhus confer long-lasting immunity; reinfection with either disease is extremely rare.

The prognosis of plague depends on the form of the disease and the promptness of treatment. Untreated bubonic plague has a mortality rate of 50–90% untreated pneumonic plague has a mortality rate of 100%. Treated bubonic plague has a mortality rate of 10–20% septicemic plague, 20–25%; and pneumonic plague, 50%. The mortality rate of bubonic plague in cats is about 60%

KEY TERMS

Ectoparasite—Any parasite that lives on the surface of its host. Fleas are ectoparasites.

Emerging infectious disease (EID)—An infectious disease whose incidence has increased within the last 35 years and may increase further in the near future.

Endemic—Referring to a disease that is maintained in a population without the need for external inputs. The infection neither dies out nor increases exponentially.

Murine typhus—A form of typhus that is transmitted by fleas carried by rats. It is also called endemic typhus, and should be distinguished from epidemic typhus, which is carried by body lice.

Notifiable disease—Any disease that is required by law to be reported to public health authorities. In the United States, the CDC maintains a list of nationally notifiable diseases monitored by the National Notifiable Diseases Surveillance System (NNDSS).

Vector—In epidemiology, any person, animal, or microorganism that conveys an infectious disease organism to another living organism.

Zoonosis (plural, zoonoses)—Any disease that can be transmitted from other animals to humans, or from humans to other animals.

Prevention

There are no vaccines for plague, murine typhus,, or cat-scratch fever in the United States as of 2014.

Preventive measures recommended by the CDC include:

- Treating household pets with flea-repellent medications as recommended by the veterinarian; however, never use flea products intended for dogs to treat cats. Flea treatments are highly species-specific.
- Removing brush, junk, woodpiles, and similar rodent hiding places from the area surrounding the home.
- Keeping food for domestic pets strictly indoors, and keeping food for farm animals in rodent-proof containers.
- Rodent-proofing the house, garage, and any outbuildings. Agricultural extension services can usually provide detailed advice on rodent-proofing outdoor structures.
- Using insect repellents like DEET (on skin) and permethrin (on clothing) when working or hiking outdoors.
- Not allowing pets to roam freely outdoors. Dogs should be walked on a leash, and cats should be kept indoors as much as possible. Pets that are allowed to roam freely should not be allowed to sleep on human beds when indoors, and sick or ailing pets should be taken to the veterinarian at once for diagnosis and treatment. Pets' indoor bedding should be kept as clean as possible and laundered frequently.
- Wearing gloves at all times when handling or skinning dead animals.

Rebecca J. Frey, PhD

Flesh-eating disease

Definition

Flesh-eating disease is also commonly called necrotizing fasciitis, a rare condition in which bacteria destroy tissues underlying the skin. This tissue death, called **necrosis** or **gangrene**, spreads rapidly. This disease can be fatal in as little as 12 to 24 hours.

Description

Although the term is technically incorrect, flesh-eating disease is an apt descriptor: The infection appears to devour body tissue. Media reports increased in the middle and late 1990s, but the disease is not new. Hippocrates described it more than three millennia ago and thousands of reports exist from the Civil War. Approximately 500 to 1,500 cases of necrotizing fasciitis occur in the United States each year.

Flesh-eating disease is divided into two types. Type I is caused by anaerobic bacteria, with or without the presence of aerobic bacteria. Type II, also called hemolytic streptococcal gangrene, is caused by group A streptococci; other bacteria may or may not be present. The disease may also be called synergistic gangrene.

Type I fasciitis typically affects the trunk, abdomen, and genital area. For example, Fournier's gangrene is a "flesh-eating" disease in which the infection encompasses the external genitalia. The arms and legs are most often affected in type II fasciitis, but the infection may appear anywhere.

Causes and symptoms

The two most important factors in determining whether a person will develop flesh-eating disease are: the virulence (ability to cause disease) of the bacteria and the susceptibility (ability of a person's immune system to respond to infection) of the person who becomes infected with this bacteria.

In nearly every case of flesh-eating disease, a skin injury precedes the disease. As bacteria grow beneath the skin's surface, they produce toxins. These toxins destroy superficial fascia, subcutaneous fat, and deep fascia. In some cases, the overlying dermis and the underlying muscle are also affected.

Initially, the infected area appears red and swollen and feels hot. The area is extremely painful, which is a prominent feature of the disease. Over the course of hours or days, the skin may become blue-gray, and fluid-filled blisters may form. As nerves are destroyed the area becomes numb. An individual may go into **shock** and develop dangerously low blood pressure. Multiple organ failure may occur, quickly followed by death.

KEY TERMS

Aerobic bacteria—Bacteria that require oxygen to live and grow.

Anaerobic bacteria—Bacteria that require the absence of oxygen to live and grow.

CT scan (computed tomography scan)—Cross-sectional x rays of the body are compiled to create a three-dimensional image of the body's internal structures.

Debridement—Surgical procedure in which dead or dying tissue is removed.

Dermis—The deepest layer of skin.

Fascia, deep—A fibrous layer of tissue that envelopes muscles.

Fascia, superficial—A fibrous layer of tissue that lies between the deepest layer of skin and the subcutaneous fat.

Gangrene—An extensive area of dead tissue.

Hyperbaric oxygen therapy—A treatment in which the patient is placed in a chamber and breathes oxygen at higher-than-atmospheric pressure. This high-pressure oxygen stops bacteria from growing and, at high enough pressure, kills them.

Magnetic resonance imaging (MRI)—An imaging technique that uses a large circular magnet and radio waves to generate signals from atoms in the body. These signals are used to construct images of internal structures.

Necrosis—Abnormal death of cells, potentially caused by disease or infection.

Subcutaneous—Referring to the area beneath the skin.

Diagnosis

The appearance of the skin, paired with **pain** and **fever** raises the possibility of flesh-eating disease. An x ray, **magnetic resonance imaging** (MRI), or **computed tomography scans** (CT scans) of the area reveals a feathery pattern in the tissue, caused by accumulating gas in the dying tissue. Necrosis is evident during exploratory surgery, during which samples are collected for bacterial identification.

Treatment

Rapid, aggressive medical treatment, specifically, antibiotic therapy and surgical **debridement**, is imperative. **Antibiotics** may include penicillin, an aminoglycoside or third-generation cephalosporin, and clindamycin or metronidazole. **Analgesics** are employed for pain control. During surgical debridement, dead tissue is stripped away. After surgery, patients are rigorously monitored for continued infection, shock, or other complications. If available, **hyperbaric oxygen therapy** has also be used.

Prognosis

Flesh-eating disease has a fatality rate of about 30%. Diabetes, arteriosclerosis, **immunosuppression**, **kidney disease**, **malnutrition**, and **obesity** are connected with a poor prognosis. Older individuals and intravenous drug users may also be at higher risk. The

WWW.BOOKBAZ.IR

infection site also has a role. Survivors may require **plastic surgery** and may have to contend with permanent physical disability and psychological adjustment.

Prevention

Flesh-eating disease, which occurs very rarely, cannot be definitively prevented. The best ways to lower the risk of contracting flesh-eating disease are:

- take care to avoid any injury to the skin that may give the bacteria a place of entry
- when skin injuries do occur, they should be promptly washed and treated with an antibiotic ointment or spray
- people who have any skin injury should rigorously attempt to avoid people who are infected with streptococci bacteria, a bacteria that causes a simple strep throat in one person may cause flesh-eating disease in another
- have any areas of unexplained redness, pain, or swelling examined by a doctor, particularly if the affected area seems to be expanding

Flower remedies

Definition

Flower remedies are specially prepared flower essences, containing the healing energy of plants. They are prescribed according to a patient's emotional disposition, as ascertained by the therapist, doctor, or patients themselves.

Purpose

Flower remedies are more homeopathic than herbal in the way they work, effecting energy levels rather than chemical balances. They have been described as "liquid energy." The theory is that they encapsulate the flowers' healing energy, and are said to deal with and overcome negative emotions, and so relieve blockages in the flow of human energy that can cause illness.

Description

Origins

Perhaps the most famous and widely used system is the Bach flower remedies. This system originated in the 1920s when British physician and bacteriologist, Dr. Edward Bach (1886–1936), noticed that patients with physical complaints often seemed to be suffering from **anxiety** or some kind of negative emotion. He concluded that assessing a patient's emotional disposition and prescribing an appropriate flower essence could treat the physical illness. Bach was a qualified medical doctor, but he also practiced homeopathy.

As a result of his own serious illness in 1917, Bach began a search for a new and simple system of medicine that would treat the whole person. In 1930, he gave up his flourishing practice on Harley Street at the Royal London Homeopathic Hospital and moved to the countryside to devote his life to this research. At this point, he ceased to dispense the mixture of homeopathy and allopathic medicine that he had been using. Instead, he began investigating the healing properties of plant essences and discovered that he possessed an "intuition" for judging the properties of each flower. Accordingly, he developed the system of treatment that bears his name, and is also the foundation for all other flower-remedy systems.

The Bach Flower Remedies were ostensibly the only system of significance from the 1920s until in the 1970s, when there was a renewed interest in the subject by doctors working in the field of natural medicine. Perhaps the most notable was Dr. Richard Katz, who was seeking new methods of dealing with modern **stress** and the resulting ailments. He focused on the concept of a psychic, psychological effect and chose to pursue this line of research.

In 1979, Katz founded the Flower Essence Society in California, (FES). This society pledged to further the research and development of Bach's principles. FES hosts a database of more than 100 flower essences from more than 50 countries. FES is now an international organization of health practitioners, researchers, students, and others concerned with flower essence therapy.

EDWARD BACH (1886–1936)

Edward Bach was a graduate of University College Hospital (MB, BS, MRCS) in England. He left his flourishing Harley Street practice in favor of homeopathy, seeking a more natural system of healing than allopathic medicine. He concluded that healing should be as simple and natural as the development of plants, which were nourished and given healing properties by earth, air, water, and sun.

Bach believed that he could sense the individual healing properties of flowers by placing his hands over the petals. His remedies were prepared by floating summer flowers in a bowl of clear stream water exposed to sunlight for three hours.

He developed 38 remedies, one for each of the negative states of mind suffered by human beings, which he classified under seven group headings: fear, uncertainty, insufficient interest in present circumstances, loneliness, over-sensitivity to influences and ideas, despondency or despair, and overcare for the welfare of others. The Bach remedies can be prescribed for plants, animals, and other living creatures as well as human beings.

The society has connections with an estimated 50,000 active practitioners from around the world, who use flower essence therapy as part of their treatment. FES encourages the study of the plants themselves to determine the characteristics of flower essences. They are compiling an extensive database of case studies and practitioner reports of the use of essences therapeutically, allowing verification and development of the original definitions. They are also engaged in the scientific study of flower essence therapy.

FES says they have developed the theories of Paracelsus and Goethe who researched the "signatures" and "gestures" of botanical specimens, on the premise that the human body and soul are a reflection of the system of nature. FES plant research interprets the therapeutic properties of flower essences according to these insights.

In this regard, they have devised 12 "windows of perception" for monitoring the attributes of plants. Each of these windows reveals an aspect of the plant's qualities, although they maintain that what they are seeking is a "whole which is greater than the sum of its parts." The 12 windows are not considered independent classifications, but more of a blended tapestry of views of the qualities that each plant possesses.

The first window is concerned with the "form" of a plant—its shape classification. The second focuses on its "gesture" or spatial relationship. The third window is a plant's botanical classification: The Flower Essence Society maintains that considering a plant's botanical family is essential to obtaining an overview of its properties as a flower essence. The fourth window concerns the time orientation of a particular specimen regarding the daily and seasonal cycles. Why do some flowers bloom at different times of the day, while others, such as the evening primrose, respond to the moon? The fifth window observes a plant's relationship to its environment. Where a plant chooses to grow, and where it cannot survive, reveals much about its qualities. The sixth window observes a plant's relationship to the Four Elements and the Four Ethers, as FES maintains that plants exist in one of the elemental or etheric forces in addition to their physical life. "Elements" refers to those developed by the Greeks, as opposed to the modern concept of "molecular building blocks." It seems that commonly, two elements predominate in a plant, indicating a polarity of qualities, while two can be said to be recessive. The seventh window relates to a plant's relationship with the other kingdoms of nature: mineral, animal, and human, while the eighth relates to the color and color variations of a plant. Katz explains how the language of color tells us so much about the "soul qualities" of a plant. The ninth window concerns all other sensory perceptions of a plant, such as fragrance, texture, and taste. The tenth window involves assessing the chemical substances and properties; the eleventh studies medicinal and herbal uses, as by studying the physical healing properties of plants, we can also understand something of their more subtle effects on the soul. Finally, the twelfth window involves the study of the lore, mythology, folk wisdom, and spiritual and ritual qualities associated with a particular plant. Katz relates how in the past, human beings were more in touch with the natural world, and the remnants of this unconscious plant wisdom live on in the form of folklore, mythology, and so on.

Because flower remedies operate on approximately the same principles as homeopathy, practitioners quite often prescribe the two therapies in conjunction with each other. They can also be used concurrently with allopathic medicine.

The system consists of 38 remedies, each for a different disposition. The basic theory is that if the remedy for the correct disposition is chosen, the physical illness resulting from the present emotional state can then be cured. There is a rescue remedy made up of five of the essences—cherry plum, clematis, impatiens,

WWW.BOOKBAZ.IR

rock star, and star of Bethlehem—that is recommended for the treatment of any kind of physical or emotional **shock**. Therapists recommended that rescue remedy be kept on hand to help with all emergencies.

The 38 Bach remedies are:

- agrimony: puts on a cheerful front, hides true feelings, and worries or problems
- aspen: feelings of apprehension, dark foreboding, and premonitions
- beech: critical, intolerant, picky
- centaury: easily comes under the influence of others, weak willed
- cerato: unsure, no confidence in own judgement, intuition, and seeks approval from others
- cherry plum: phobic, fear of being out of control, and tension
- chestnut bud: repeats mistakes, does not learn from experience
- chicory: self-centered, possessive, clingy, demanding, self pity
- clematis: absent minded, dreamy, apathetic, and lack of connection with reality
- crab apple: a "cleanser" for prudishness, self–disgust, feeling unclean
- elm: a sense of being temporarily overwhelmed in people who are usually capable and in control
- gentian: discouraged, doubting, despondent
- gorse: feelings of pessimism, accepting defeat
- heather: need for company, talks about self, and concentrates on own problems
- holly: jealousy, envy, suspicion, anger, and hatred
- honeysuckle: reluctance to enter the present and let the past go
- hornbeam: reluctant to face a new day, weary, can't cope (mental fatigue)
- impatiens: impatience, always in a hurry, and resentful of constraints
- larch: feelings of inadequacy and apprehension, lack of confidence and will to succeed
- mimulus: fearful of specific things, shy, and timid
- mustard: beset by "dark cloud" and gloom for no apparent reason
- oak: courageous, persevering, naturally strong but temporarily overcome by difficulties
- olive: for physical and mental renewal, to overcome exhaustion from problems of long–standing
- pine: for self–reproach, always apologizing, assuming guilt
- red chestnut: constant worry and concern for others
- rock rose: panic, intense alarm, dread, horror
- rock water: rigid–minded, self–denial, restriction
- scleranthus: indecision, uncertainty, fluctuating moods
- star of Bethlehem: consoling, following shock or grief or serious news
- sweet chestnut: desolation, despair, bleak outlook
- vervain: insistent, fanatical, over–enthusiastic
- vine: dominating, overbearing, autocratic, tyrannical
- walnut: protects during a period of adjustment or vulnerability
- water violet: proud, aloof, reserved, enjoys being alone
- white chestnut: preoccupation with worry, unwanted thoughts
- wild oat: drifting, lack of direction in life
- wild rose: apathy, resignation, no point in life
- willow bitter: resentful, dissatisfied, feeling life is unfair

Originally, Bach collected the dew from chosen flowers by hand to provide his patients with the required remedy. This became impractical when his treatment became so popular that production could not keep up with demand. He then set about finding a way to manufacture the remedies, and found that floating the freshly picked petals on the surface of spring water in a glass bowl and leaving them in strong sunlight for three hours produced the desired effect. Therapists explain that the water is "potentized" by the essence of the flowers. The potentized water can then be bottled and sold. For more woody specimens, the procedure is to boil them in a sterilized pan of water for 30 minutes. These two methods produce "mother tinctures" and the same two methods devised by Bach are still used today. Flower essences do not contain any artificial chemical substances, except for alcohol preservative.

Bach remedies cost around $10 each, and there is no set time limit for treatment. It may take days, weeks, or in some cases months. Flower essences cost around $6 each, and there is also no set time for the length of treatment, or the amount of essences that may be taken. These treatments are not generally covered by medical insurance.

Precautions

Bach remedies and flower essences are not difficult to understand, and are considered suitable for self administration. The only difficulty may be in finding the correct suggested remedy, as it can sometimes be tricky to pinpoint an individual's emotional

KEY TERMS

Aura—Emanation of light from living things (plants and animals) that can be recorded by Kirlian photography.

Essence—The constituent of a plant that determines its characteristics.

Potentize—The process of transferring the healing energy of a plant into spring water.

Window—A perspective adopted to assess the property of a given plant.

disposition. They are even safe for babies, children, and animals. An important aspect of treatment with flower remedies, is that if you feel instinctively that you need a particular remedy, you are encouraged to act on that instinct. However, it is advisable not to continue a particular remedy once you feel you no longer need it, and to try a different one if you feel that progress is not being made.

The remedies are administered from a stoppered bottle and need to be diluted. Individuals sensitive to alcohol can apply the concentrate directly to temples, wrists, behind the ears, or underarms. They should be kept in a cool dark place; like this they should last indefinitely. However, a diluted remedy should not be kept longer than three weeks. Two drops of each diluted remedy should be taken four times a day, including first thing in the morning and last thing at night. If the rescue remedy is being used, four drops should be used instead. Most therapists recommend that they be taken in spring water, but the remedy can be taken directly from the bottle, if care is taken that the dropper does not touch the tongue, as this would introduce bacteria that would spoil the remedy.

It is not recommended that more than six or seven Bach remedies be used at any one time. Instead, it is preferable to divide a larger amount up into two lots to ensure the optimum effectiveness of the remedies. No combination, or amount of combinations of the remedies can cause any harm, rather they become less effective.

Unlike FES, the Bach Centre does not encourage research to "prove" that the remedies work, preferring that people find out for themselves. They strive to keep the use of the Bach remedies as simple as possible, and to this end they do not keep case records. Bach warned before he died that others would try to change his work and make it more complicated. He was determined to keep it simple so that anyone could use it, and that is why he limited the system to only 38 remedies. The Centre points out that many who have used Bach's research as a starting point have added other remedies to the list, even some that Bach himself rejected.

Side effects

Flower remedies or essences are generally regarded as being totally safe, and there are no known side effects apart from the rare appearance of a slight rash, which is not a reason to discontinue treatment, says the Bach Centre.

Results

Bach flower remedies and flower essences have not yet officially won the support of allopathic medicine, despite the fact that more and more medical doctors are referring patients for such treatments on the strength of personal conviction. However, it is difficult to discount the scores of testimonials. Some practitioners refer skeptics to the research that has been done regarding the "auras" of living things. Theoretically, the stronger the aura, the more alive an organism is. Flower essences have very strong auras.

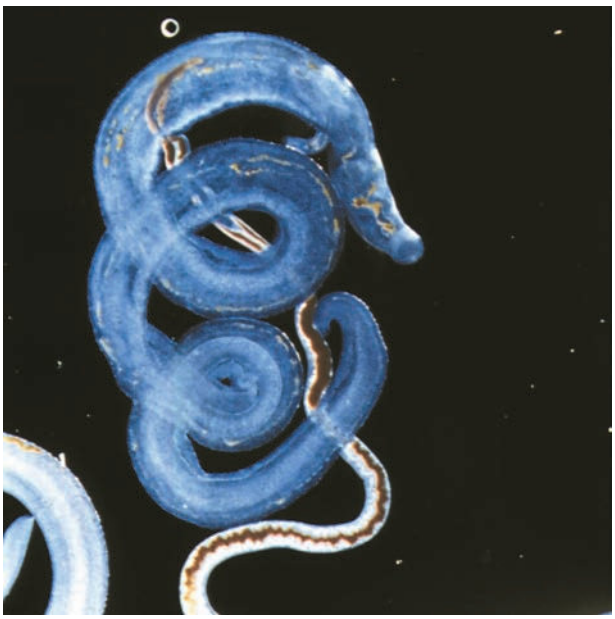
Fluke infections

Definition

Fluke infections are diseases of the digestive tract and other organ systems caused by several different species of parasitic flatworms (trematodes) that have

WWW.BOOKBAZ.IR



A micrograph of adult intestinal blood flukes, *Schistosoma mansoni*. Humans can become infected while bathing or working in contaminated water. *(Photo Researchers, Inc.)*

complex life cycles involving hosts other than human beings. Trematode comes from a Greek word that means having holes and refers to the external suckers that adult flukes use to draw nourishment from their hosts. Fluke infections are contracted by eating uncooked fish, plants, or animals from fluke-infected waters. Symptoms vary according to the type of fluke infection.

Description

In humans, fluke infections can be classified according to those diseases caused by liver flukes and those caused by lung flukes. Diseases caused by liver flukes include fascioliasis, opisthorchiasis, and clonorchiasis. Cases of liver fluke infection have been reported in Europe and the United States, as well as the Middle East, China, Japan, and Africa. Diseases caused by lung flukes include paragonimiasis. Paragonimiasis is a common infection in the Far East, Southeast Asia, Africa, Central and South America, Indonesia, and the Pacific Islands. It is estimated that between 40 million and 100 million people worldwide suffer from either liver or lung fluke infections.

In their adult stage, liver and lung flukes are symmetrical in shape, ranging between 0.25–1 in in length, and look somewhat like long, plump leaves or blades of grass. They enter through the mouth and can infect any person at any age.

Causes and symptoms

The symptoms of fluke infection differ somewhat according to the type of fluke involved. All forms of liver and lung fluke infection, however, have the following characteristics:

- most persons who get infected do not develop symptoms (asymptomatic)
- the early symptoms of an acute fluke infection are not unique to these diseases alone (nonspecific symptoms)
- infection does not confer immunity against re-infection by the same species or infection by other species of flukes
- infection is usually associated with eating uncooked fish, plants, or animals that live in fresh water

Fascioliasis

Fascioliasis is caused by *Fasciola hepatica*, the sheep liver fluke. The fluke has a three-part life cycle that begins when eggs from a host's feces are deposited in water. The eggs release free-swimming larvae (miracidia) that infect snails. The snails then release free-swimming larvae with tails (cercariae) that form cysts containing larvae in the infective stage (metacercariae) on vegetation growing in fresh water. Humans become infected when they eat watercress, water chestnuts, or other plants covered with the encysted metacercariae.

When a person eats contaminated plants, the cysts are broken open in the digestive system, and the metacercariae leave their cysts, pass through the wall of the intestine, and enter the liver, where they cause inflammation and destroy tissue. After a period of 10–15 weeks in the liver, the adult flukes move to the bile ducts and produce eggs. Acute fascioliasis is marked by abdominal **pain** with **headache**, loss of appetite, anemia, and **vomiting**. Some patients develop **hives**, muscle pains, or a yellow-color to the skin and whites of the eyes (**jaundice**). Chronic forms of the disease may produce complications, including blockage of the bile ducts or the migration of adult flukes to other parts of the body.

Opisthorchiasis and clonorchiasis

These infections are caused by *Clonorchis sinensis*, the Chinese liver fluke, and *Opisthorchis viverrini* or *O. felineus*. The diseases are widespread, affecting more than 20 million people in Japan, China, Southeast Asia, and India. The life cycle of these liver flukes is similar to that of *F. hepatica* except that the etacercariae are encysted in freshwater fish rather

KEY TERMS

Aspirator—A medical instrument that uses suction to withdraw fluids from the lungs, digestive tract, or other parts of the body for laboratory testing.

Asymptomatic—Persons who carry a disease and are usually capable of transmitting the disease but, who do not exhibit symptoms of the disease are said to be asymptomatic.

Cercaria (plural, cercariae)—An intermediate-stage of the fluke larva, released into water by infected snails.

Cross-reaction—A reaction that occurs in blood testing when a disease agent reacts to the specific antibody for another disease agent. Cross-reactions are common in blood tests for fluke infections because the different species are closely related.

Encysted—Enclosed in a cyst or capsule. Flukes spend part of their life cycle as encysted larvae.

Fluke—A parasitic flatworm that has external suckers. Flukes are sometimes called trematodes.

Host—The living animal that supplies nutrition to a parasite.

Jaundice—Yellowing of the skin and the whites of the eyes as a result of excess bile in the blood due to an improperly functioning liver.

Metacercaria (plural, metacercariae)—The encysted stage of a fluke larva that produces infection in human beings.

Miracidium (plural, miracidia)—The free-swimming larval form in the life cycle of the liver fluke.

Parasite—An organism that lives on or inside an animal of a different species and feeds on it or draws nutrients from it.

Trematode—Parasitic flatworms or another name for fluke, taken from a Greek word that means having holes.

than on plants. Dogs, cats, and other mammals that eat raw fish can be infected with opisthorchiasis and clonorchiasis.

The symptoms of opisthorchiasis and clonorchiasis are similar to those of fascioliasis and include both acute and chronic forms. In acute infection, the patient may be tired, have a low-grade **fever**, pains in the joints, a swollen liver, abdominal pain, and a skin rash. The acute syndrome may be difficult to diagnose because the fluke eggs do not appear in the patient's stool for three to four weeks after infection. Patients with the chronic form of the disease experience a loss of appetite, **fatigue**, low-grade fever, **diarrhea**, and an enlarged liver that feels sore when the abdomen is pressed.

Paragonimiasis

Paragonimiasis is caused by a lung fluke, either *Paragonimus westermani* or *P. skrjabini*. These flukes are larger than liver flukes and infect meat- or fish-eating animals as well as humans. Their life cycle is similar to that of liver flukes except that their encysted larvae infect crabs and crayfish rather than plants or fish. Humans can ingest the encysted metacercariae from drinking contaminated water or eating raw or undercooked crabs and crayfish.

In humans, the metacercariae are released from their cysts in the small intestine and migrate to the lungs or the brain in 1% of cases. In the lungs, the flukes lay their eggs and form areas of inflammation covered with a thin layer of fibrous tissue. These areas of infection may eventually rupture, causing the patient to **cough** up fluke eggs, blood, and inflamed tissue. The period between the beginning of the infection and the appearance of the eggs during coughing is about six weeks. Patients with lung infections may have chest pain and fever as well as rust-colored or bloody sputum. Lung infections can lead to **lung abscess**, **pneumonia**, or **bronchitis**. Patients with fluke infections of the brain may experience seizures or a fatal inflammation of brain tissue called encephalitis. Some patients also develop diarrhea and abdominal pain or lumps under the skin that contain adult flukes.

Diagnosis

Diagnosis of fluke infections is based on a combination of the patient's history, particularly travel or residence in areas known to have flukes, and identification of the fluke's eggs or adult forms. In some patients, the eggs are found in fluid from the lungs, bile duct, or small intestine. Samples of these fluids can be obtained with a suction instrument (aspirator). Because most types of fluke infections are rare in the United States, stool specimens or body fluid samples may need to be sent to a laboratory with experts in

WWW.BOOKBAZ.IR

unusual diseases or conditions to identify the specific parasite. In some cases, adult flukes may be found in the patient's stools, vomit, sputum, or skin lumps (for lung flukes). In the case of lung flukes, it is important for the doctor to rule out **tuberculosis** as a possible diagnosis. A tuberculosis skin test and **chest x ray** will usually be sufficient to do this.

Blood tests may be useful in diagnosing fluke infections, but their usefulness is limited because of cross-reactions. A cross-reaction occurs in blood testing when a particular disease agent reacts with antibodies specific to another disease agent. This result means that the doctor may know that the person is infected by flukes but cannot tell from the blood test alone which specific type of fluke is causing the disease. In addition, blood tests for fluke infections cannot distinguish between past and current infections. In some cases, sophisticated imaging techniques, such as **computed tomography scans** (CT scans) or **ultrasound** scans of the patient's chest or brain (for lung flukes) or abdomen (for liver flukes), are useful in confirming a diagnosis of fluke infection.

Treatment

Liver and lung fluke infections are treated with medications. These include triclabendazole, praziquantel, bithionol, albendazole, and mebendazole. Praziquantel works by paralyzing the flukes' suckers, forcing them to drop away from the walls of the host's blood vessels. In the United States, bithionol is available only from the Centers for Disease Control (CDC). Depending on the species of fluke and the severity of infection, the course of treatment can vary from several days to several weeks. Cure rates vary from 50–95%. Most patients experience mild temporary side effects from these drugs, including diarrhea, **dizziness**, or headache.

Prognosis

The prognosis for recovery from liver fluke infections is good, although patients with serious infections may be more vulnerable to other diseases, particularly if significant liver damage has occurred. Most patients with lung fluke infections also recover, however, severe infections of the brain can cause death from the destruction of central nervous system or brain tissue.

Prevention

No vaccines have been developed that are effective against lung or liver fluke infections. Prevention of these infections includes the following measures:

- boiling or purifying drinking water
- avoiding raw or undercooked fish or salads made from fresh aquatic plants; all food eaten in areas with fluke infestations should be cooked thoroughly; pickling or smoking will not kill fluke cysts in fish or shellfish
- control or eradication of the snails that serve as the flukes' intermediate hosts

Fluoroquinolones

Definition

Fluoroquinolones are medicines that kill bacteria or prevent their growth.

Purpose

Fluoroquinolones are antimicrobials, medicines used to treat infections caused by microorganisms. Physicians prescribe these drugs for bacterial infections in many parts of the body. For example, they are used to treat bone and joint infections, skin infections, urinary tract infections, inflammation of the prostate, serious ear infections, **bronchitis**, **pneumonia**, **tuberculosis**, some sexually transmitted diseases (STDs), and some infections that affect people with **AIDS**.

Description

Fluoroquinolones are available only with a physician's prescription and are sold in tablet and injectable forms. Examples of these medicines are moxifloxacin (Avelox), ciprofloxacin (Cipro), ofloxacin (Floxin), levofloxacin (Levaquin), lomefloxacin (Maxaquin), norfloxacin (Noroxin), enoxacin (Penetrex), gatifloxacin (Tequin), and sparfloxacin (Zagam).

In the wake of the **anthrax** terrorist attacks in the United States in 2001, ciprofloxacin received extensive media attention because it was the only drug labeled as approved by the U.S. Food and Drug Administration (FDA) for both **prophylaxis** and treatment of inhalation anthrax (the most serious form of the disease).

However, in late October 2001, the FDA issued a notice clarifying that the antibiotic doxycycline is also approved for anthrax prophylaxis and that doxycycline and amoxicillin are also approved for treatment for all forms of anthrax. The FDA encouraged companies to update labeling of these products with this previously unspecified information.

Recommended dosage

The recommended dosage depends on the type and strength of fluoroquinolone, and the kind of infection for which it is being taken. Check with the physician who prescribed the drug or the pharmacist who filled the prescription for the correct dosage.

To make sure the infection clears up completely, take the medicine for as long as it has been prescribed. Do not stop taking the drug just because symptoms begin to improve. Symptoms may return if the drug is stopped too soon.

Fluoroquinolones work best when they are at constant levels in the blood. To help keep levels constant, take the medicine in doses spaced evenly through the day and night. Do not miss any doses. For best results, take this medicine with a full glass of water and drink several more glasses throughout the day, every day during treatment with the drug. The extra water will help prevent some side effects. Some fluoroquinolones should be taken on an empty stomach; others may be taken with meals. Check package directions or ask the physician or pharmacist for instructions on how to take the medicine.

Precautions

An important precaution for any antibiotic is that unnecessary use or abuse of **antibiotics** can encourage drug-resistant strains of bacteria to develop and proliferate. These drug-resistant strains then become difficult, or even impossible, to treat. Bacteria found in hospitals appear to have become especially resilient, and are causing increasing difficulty for patients and the doctors treating them. Following the U.S. 2001 anthrax attacks, for example, the American Medical Association urged its members not to prescribe ciprofloxacin unnecessarily. One fear is that the overuse of the drug could reduce its effectiveness against infections such as **typhoid fever**, hospital-acquired pneumonia, and others.

Research suggests that fluoroquinolones may cause bone development problems in children and teenagers. Infants, children, teenagers, pregnant women, and women who are **breastfeeding** should not take this medicine unless directed to do so by a physician.

Although such side effects are rare, some people have had severe and life-threatening reactions to fluoroquinolones. Call a physician immediately if any of these signs of a dangerous reaction occur:

- swelling of the face and throat
- swallowing problems
- shortness of breath
- rapid heartbeat
- tingling of fingers or toes
- itching or hives
- loss of consciousness

Some fluoroquinolones may weaken the tendons in the shoulder, hand, or heel, making the tendons more likely to tear. Anyone who notices **pain** or inflammation in these or other tendon areas should stop taking the medicine immediately and call a physician. Rest and avoid **exercise** until the physician determines whether the tendons are damaged. If the tendons are torn, surgery may be necessary to repair them.

These medicines make some people feel drowsy, dizzy, lightheaded, or less alert. Anyone who takes these drugs should not drive, use machines or do anything else that might be dangerous until they have found out how the drugs affect them.

This medicine may increase sensitivity to sunlight. Even brief exposure to sun can cause a severe **sunburn** or a rash. While being treated with fluoroquinolones, avoid being in direct sunlight, especially between 10 a.m. and 3 p.m.; wear a hat and tightly woven clothing that covers the arms and legs; use a sunscreen with a skin protection factor (SPF) of at least 15; protect the lips with a sun block lipstick; and do not use **tanning** beds, tanning booths, or sunlamps.

Do not take **antacids** that contain aluminum, **calcium**, or magnesium at the same time as fluoroquinolones. The antacids may keep the fluoroquinolones from working as they should. If antacids are needed, take them at least two hours before or two hours after taking norfloxacin or ofloxacin, at least four hours before or two hours after taking ciprofloxacin. Follow the same instructions for taking sucralfate (Carafate), a medicine used to treat stomach **ulcers** and other irritation in the digestive tract and mouth.

Anyone who has had unusual reactions to fluoroquinolones or related medicines such as cinoxacin (Cinobac) or nalidixic acid (NegGram) in the past should let his or her physician know before taking

WWW.BOOKBAZ.IR

KEY TERMS

Bacteria—Tiny, one-celled forms of life that cause many diseases and infections.

Bronchitis—Inflammation of the air passages of the lungs.

Digestive tract—The stomach, intestines, and other parts of the body through which food passes.

Inflammation—Pain, redness, swelling, and heat that usually develop in response to injury or illness.

Microorganism—An organism that is too small to be seen with the naked eye.

Pneumonia—A disease in which the lungs become inflamed. Pneumonia may be caused by bacteria, viruses, or other organisms, or by physical or chemical irritants.

Prostate—A donut-shaped gland in males below the bladder that contributes to the production of semen.

Sexually transmitted disease (STD)—A disease that is passed from one person to another through sexual intercourse or other intimate sexual contact.

Tendon—A tough band of tissue that connects muscle to bone.

Tuberculosis—An infectious disease that usually affects the lungs, but may also affect other parts of the body. Symptoms include fever, weight loss, and coughing up blood.

Urinary tract—The passage through which urine flows from the kidneys out of the body.

the drugs again. The physician should also be told about any **allergies** to foods, dyes, preservatives, or other substances.

Before using fluoroquinolones, people with any of these medical problems should make sure their physicians are aware of their conditions:

- kidney disease
- liver disease with kidney disease
- diseases of the brain or spinal cord, including hardening of the arteries in the brain, epilepsy, and other seizure disorders

Taking fluoroquinolones with certain other drugs may affect the way the drugs work or may increase the chance of side effects.

Risks

The most common side effects are mild **diarrhea**, nausea, **vomiting**, stomach or abdominal pain, **dizziness**, drowsiness, lightheadedness, nervousness, sleep problems, and **headache**. These problems usually go away as the body adjusts to the drug and do not require medical treatment unless they are bothersome.

More serious side effects are not common, but may occur. If any of the following side effects occur, check with a physician immediately:

- skin rash or other skin problems such as itching, peeling, hives, or redness
- fever
- agitation or confusion
- hallucinations
- shakiness or tremors
- seizures or convulsions
- tingling of fingers or toes
- pain where the medicine was injected (lasting after the injection)
- pain in the calves, spreading to the heels
- swelling of the calves or lower legs
- swelling of the face or neck
- swallowing problems
- rapid heartbeat
- shortness of breath
- loss of consciousness

Other rare side effects may occur. Anyone who has unusual symptoms after taking fluoroquinolones should get in touch with his or her physician.

Fluoroquinolones may interact with other medicines. When this happens, the effects of one or both of the drugs may change or the risk of side effects may be greater. Anyone who takes fluoroquinolones should let the physician know all other medicines he or she is taking. Among the drugs that may interact with fluoroquinolones are:

- antacids that contain aluminum, calcium, or magnesium
- medicines that contain iron or zinc, including multivitamin and mineral supplements
- sucralfate (Carafate)

- caffeine
- blood thinning drugs such as warfarin (Coumadin)
- airway opening drugs (bronchodilators) such as aminophylline, theophylline (Theo-Dur and other brands), and oxtriphylline (choledyl and other brands)
- didanosine (Videx), used to treat HIV infection.

This list does not include every drug that may interact with fluoroquinolones. Be sure to check with a physician or pharmacist before combining fluoroquinolones with any other prescription or nonprescription (over-the-counter) medicine.

Folate

Definition

Folate is a naturally occurring water-soluble vitamin that the body needs to remain healthy. **Folic acid** is a stable synthetic form of folate that is found in dietary supplements and is added to fortified foods, such as flour and cereal. Humans cannot make folate or folic acid, so they must get it from foods in their diet or as a dietary supplement. Folic acid and folate are both converted into an active form that the body can use, although folic acid is more easily used (more bioavailable) in the body. Folic acid is also called vitamin B_9.

Purpose

Folate is necessary to create new DNA (genetic material) and RNA when cells divide. It plays a critical role in developing healthy red blood cells. Folate also helps protect DNA from damage that may lead to diseases such as cancer. Along with **vitamins** B_6 and B_{12}, folate helps regulate the level of the amino acid **homocysteine** in the blood. Homocysteine regulation is related to cardiovascular health. In the fetus, folate is necessary for the proper development of the brain and spinal cord.

Description

Folate is one of eight B-complex vitamins. Its function is closely intertwined with that of vitamins B_6 and B_{12}. Folate, from the Latin word *folium*, meaning leaf, was discovered in the late 1930s in yeast, and later found in spinach and other green leafy vegetables and in liver. Starting in 1998, the U.S. Food and Drug Administration (FDA) required certain foods, such as flour, corn meal, bread, cereal, rice, and pasta, to be fortified with a folic acid. In Canada and Chile, fortification of flour is mandatory.

Folate's role in health

Folate is essential for the normal development of the neural tube in the fetus. The neural tube develops into the brain and spinal cord. It closes between the third and fourth week after conception. Too little folate at this time can lead to serious malformations of the spine (**spina bifida**) and the brain (anencephaly). Because many women do not realize that they are pregnant so soon after conception, the United States has included folic acid in its fortified foods program. Adding folic acid to common foods made with grains has substantially reduced the number of babies born with neural tube defects in the United States.

The body also needs folate to produce healthy red blood cells. When not enough folate is present, the red blood cells do not divide and instead grow to be abnormally large. These malformed cells have a reduced ability to carry oxygen to other cells in the body, a condition known as megaloblastic anemia. Folate also aids in the production of other new cells. Adequate supplies of folate are especially important in fetuses and infants because they are growing rapidly, but, since the lifespan of a red blood cell is only about four months, both children and adults need a continuous supply of folate throughout life to create healthy new replacement blood cells.

Folate acts together with vitamin B_6 and vitamin B_{12} to lower the level of homocysteine in the blood. Homocysteine is an amino acid that is naturally produced when the body breaks down protein. Moderate to high levels of homocysteine in the blood are potentially linked to an increased risk of cardiovascular disease (e.g., atherosclerosis, **heart attack**, **stroke**).

WWW.BOOKBAZ.IR

The trio of folate, vitamin B_6, and vitamin B_{12} lower homocysteine levels. However, it is not clear whether taking large doses of these vitamins, either alone or in combination, will prevent **heart disease** from developing in healthy individuals. The official position of the American Heart Association in 2012 stated, "We don't recommend widespread use of folic acid and B vitamin supplements to reduce the risk of heart disease and stroke. We advise a healthy, balanced diet that's rich in fruits and vegetables, whole grains, and fat-free or low-fat dairy products."

Damage to DNA appears to contribute to the development of many different cancers. Because folate helps protect against DNA damage, researchers have looked at whether it can reduce the risk of developing cancer. Results are mixed, with benefits seen for some cancers but not for others. The American Cancer Society position in 2012 was as follows: "Low levels of folic acid in the blood have been linked with higher rates of colorectal cancer and some other types of cancer, as well as with certain **birth defects**. It is not clear whether consuming recommended (or higher) amounts of folic acid—from foods or in supplements—can lower cancer risk in some people. These issues are being studied. High doses of folic acid can interfere with the action of some **chemotherapy** drugs, such as methotrexate."

Many clinical trials are underway to determine the safety and effectiveness of folate, both alone and in combination with other vitamins, in preventing cancer, cardiovascular disease, and dementias, such as Alzheimer's disease. Research is also underway on the effect of folate on **schizophrenia** and the feasibility of including folate in birth control pills. Individuals interested in participating in a clinical trial at no charge can find a list of open trials at http://www.clinicaltrials.gov.

Sources of folate

People need a continuous supply of folate from their diet because of the role it plays in creating new blood cells. Because folate is water-soluble, little is stored in the body, any excess is excreted in urine. Since the folic acid fortification program began in 1998, most healthy Americans get enough folate from their diet. The exception is pregnant women who should, under medical supervision, take a folic acid supplement (400 mcg for most women and higher doses for those who have already had a baby with a neural tube defect). Good natural sources of folate include beef liver, green leafy vegetables, and dried beans. Cooking animal products does not reduce the folate content much, but cooking vegetables can reduce the amount of folate by up to 40%, depending on the vegetable and the cooking method.

The following list gives the approximate folate content of some common foods:

- asparagus, cooked, 1/2 cup: 132 mcg
- spinach, cooked, 1/2 cup: 131 mcg
- turnip greens, cooked, 1/2 cup: 135 mcg
- broccoli, steamed, 1/2 cup: 85 mcg
- beets, boiled, 1/2 cup: 68 mcg
- great northern beans, cooked, 1/2 cup: 90 mcg
- pinto beans, cooked, 1/2 cup: 147 mcg
- navy beans, cooked, 1/2 cup: 127 mcg
- tomato juice, canned, 6 oz: 35 mcg
- raspberries, 1/2 cup: 16 mcg
- corn, yellow, cooked, 1/2 cup: 37 mcg
- breakfast cereal, fortified 100%, 3/4 cup: 400 mcg
- bread, white or whole wheat, 1 slice: 25 mcg
- rice, white, enriched long-grain, cooked, 1/2 cup: 65 mcg
- bread, whole wheat, 1 slice: 0.07 mg
- bread, white, enriched, 1 slice: 0.09 mg

Recommended dosage

The U.S. Institute of Medicine (IOM) of the National Academy of Sciences has developed values called Dietary Reference Intakes (DRIs) for vitamins and **minerals**. The DRIs consist of three sets of numbers. The Recommended Dietary Allowance (RDA) defines the average daily amount of the nutrient needed to meet the health needs of 97–98% of the population. The Adequate Intake (AI) is an estimate set when there is not enough information to determine an RDA. The Tolerable Upper Intake Level (UL) is the average maximum amount that can be taken daily without risking negative side effects. The DRIs are calculated for children, adult men, adult women, pregnant women, and breast feeding women.

The IOM has not set RDAs for folate in children under one year old because of incomplete scientific information. Instead, it has set AI levels for this age group. RDAs and ULs for folate are measured in micrograms (mcg). Unlike the UL for many vitamins, the UL for folate refers only to folic acid that comes from fortified food or that is in folic acid dietary supplements, multivitamins, or B-complex vitamins. There is no UL for folate found in natural plant and

animal foods. Dietary supplements containing more than 1,000 mcg (1 mg) of folic acid require a prescription. One mcg of folate from natural food sources is equal in biological activity in humans to 0.6 mcg of folic acid from supplements or fortified food.

The following are the daily RDAs and AIs and ULs for folic acid for healthy individuals:

- children birth–6 months: AI 65 mcg; UL not established
- children 7–12 months: AI 89 mcg; UL not established
- children 1–3 years: RDA 150 mcg; UL 300 mcg
- children 4–8 years: RDA 200 mcg; UL 400 mcg
- children 9–13 years: RDA 300 mcg; UL 600 mcg
- children 14–18 years: 400 RDA mcg; UL 800 mcg
- adults age 19 and older: RDA 400 mcg; UL 1,000 2mcg
- pregnant women: RDA 600 mcg; UL 1,000 mcg
- breastfeeding women: RDA 500 mcg; 1,000 mcg

Precautions

Since many pregnancies are unplanned and unrecognized until after the critical period for brain and spinal cord formation, any woman who may become pregnant should be careful to include enough folate in her diet, and folic acid supplements should be taken before and in the first trimester of **pregnancy**.

Folic acid may mask vitamin B_{12} deficiency. Folic acid supplements will reverse anemia symptoms, but they do not stop nerve damage caused by B_{12} deficiency. Permanent nerve damage may result. People with suspected folate deficiency who begin taking folic acid supplements should also be evaluated for vitamin B_{12} deficiency.

Interactions

The following is a partial list of medications that may interfere with the ability of the body to absorb and use folate. Individuals taking these medications should check with their physician about the effects they may have on folate levels in the body:

- seizure medications, such as dilantin, phenytoin, and primidone
- metformin (Fortamet, Glucophage, Glucophage XR, Riomet), used to treat type 2 diabetes
- sulfasalazine (Azulfidine, in the United States), used to treat Crohn's disease and inflammatory bowel disease
- triamterene (Dyrenium), a diuretic or "water pill"
- barbiturate sedatives
- methotrexate (Rheumatrex, Trexall), used to treat cancer, rheumatoid arthritis, and psoriasis
- drugs used to treat gastroesophageal reflux disease (GERD), such as omeprazole (Prilosec), lansoprazole (Prevacid), cimetidine (Tagamet), famotidine (Pepcid), nizatidine (Axid), or ranitidine (Zantac)

KEY TERMS

Alzheimer's disease—An incurable disease of older individuals that results in the destruction of nerve cells in the brain and causes gradual loss of mental and physical functions.

Amino acid—Molecules that are the basic building blocks of proteins.

B-complex vitamins—A group of water-soluble vitamins that often work together in the body. These include thiamin (B_1), riboflavin (B_2), niacin (B_3), pantothenic acid (B_5), pyridoxine (B_6), biotin (B_7 or vitamin H), folate (B_9), and cobalamin (B_{12}).

Celiac disease—A chronic digestive disorder in which eating foods that contain the protein gluten (found in wheat flour, rye, and barley) causes an immune reaction that damages the small intestine and interferes with the absorption of food.

Deoxyribonucleic acid (DNA)—The genetic material in cells that holds the inherited instructions for growth, development, and cellular functioning.

Dietary supplement—A product—such as a vitamin, mineral, herb, amino acid, or enzyme—that is intended to be consumed in addition to an individual's diet with the expectation that it will improve health.

Diuretic—A substance that removes water from the body by increasing urine production.

Enzyme—A protein that changes the rate of a chemical reaction within the body without being depleted in the reaction.

Megaloblastic anemia—A type of anemia characterized by abnormally large red blood cells; usually caused by folate or vitamin B_{12} deficiencies.

Ribonucleic acid (RNA)—A molecule that helps decode genetic information (DNA) and is necessary for protein synthesis.

Water-soluble vitamin—A vitamin that dissolves in water and can be removed from the body in urine.

WWW.BOOKBAZ.IR

Risks

No complications are expected when folate or folic acid is taken within recommended levels.

Folate deficiency

Most healthy people in the United States get enough folate in their diet because folate is added to many common foods, such as bread; however, this is not the case elsewhere. In Europe, low intakes are commonly reported, particularly in teenage girls and older people. Causes of folate deficiency include inadequate intake, impaired absorption (**celiac disease**, Crohn's disease, certain medications), inability of the body to use folate (enzyme deficiencies), increased folate needs (pregnancy, cancer), or increased loss or excretion (**kidney dialysis**, **alcoholism**). The elderly are the largest group at risk to develop folate deficiency.

The major symptom of folate deficiency in pregnant women is having a baby born with a brain or spinal cord abnormality. Other symptoms of folate deficiency include slow growth in infants and children; megaloblastic anemia; digestive problems, such as **diarrhea**; sore tongue; irritability; forgetfulness; and changes in mental state. These changes also have other causes and should be evaluated by a healthcare professional.

Folate overdose

Complications of excess folic acid intake at levels above 1,000 mcg daily over an extended period can include seizures in individuals taking anticonvulsant medications and general irritability and restlessness in otherwise healthy individuals.

REVISED BY TISH DAVIDSON, AM

Folic acid

Definition

Folic acid is a water-soluable vitamin belonging to the B-complex group of **vitamins**. These vitamins help the body break down complex carbohydrates into simple sugars to be used for energy. Excess B vitamins are excreted from the body rather than stored for later use. This is why sufficient daily intake of folic acid is necessary.

Description

Folic acid is also known as folate, or folacin. It is one of the nutrients most often found to be deficient in the Western diet, and there is evidence that deficiency is a problem on a worldwide scale. Folic acid is found in leafy green vegetables, beans, peas and lentils, liver, beets, brussel sprouts, poultry, nutritional yeast, tuna, wheat germ, mushrooms, oranges, asparagus, broccoli, spinach, bananas, strawberries, and cantaloupes. In 1998, the U.S. Food and Drug Administration (FDA) required food manufacturers to add folic acid to enriched bread and grain products to boost intake and to help prevent neural tube defects (NTD).

Purpose

Folic acid works together with vitamin B_{12} and vitamin C to metabolize protein in the body. It is important for the formation of red and white blood cells. It is necessary for the proper differentiation and growth of cells and for the development of the fetus. It is also used to form the nucleic acid of DNA and RNA. It increases the appetite and stimulates the production of stomach acid for digestion and it aids in maintaining a healthy liver. A deficiency of folic acid may lead to anemia, in which there is decreased production of red blood cells. This reduces the amounts of oxygen and nutrients that are able to get to the tissues. Symptoms may include **fatigue**, reduced secretion of digestive acids, confusion, and forgetfulness. During **pregnancy**, a folic acid deficiency may lead to **preeclampsia**, premature birth, and increased bleeding after birth.

People who are at high risk of strokes and **heart disease** may greatly benefit by taking folic acid supplements. An elevated blood level of the amino acid **homocysteine** has been identified as a risk factor for some of these diseases. High levels of homocysteine have also been found to contribute to problems with **osteoporosis**. Folic acid, together with vitamins B_6 and B_{12}, helps break down homocysteine, and may help reverse the problems associated with elevated levels.

Pregnant women have an increased need for folic acid, both for themselves and their child. Folic acid is necessary for the proper growth and development of the fetus. Adequate intake of folic acid is vital for the prevention of several types of **birth defects**, particularly NTDs. The neural tube of the embryo develops into the brain, spinal cord, spinal column, and the skull. If this tube forms incompletely during the first few months of pregnancy a serious, and often fatal, defect results in **spina bifida** or anencephaly. Folic acid, taken from one year to one month before conception through the first four months of pregnancy, can reduce the risk of NTDs by 50–70%. It also helps prevent a **cleft lip and palate**.

Research shows that folic acid can be used to successfully treat cervical dysplasia, a condition diagnosed by a Pap smear, of having abnormal cells in the cervix. This condition is considered to be a possible precursor to **cervical cancer**, and is diagnosed as an abnormal Pap smear. Daily consumption of 1,000 mcg of folic acid for three or more months has resulted in improved cervical cells upon repeat Pap smears.

Studies suggest that long-term use of folic acid supplements may also help prevent lung and **colon cancer**. Researchers have also found that alcoholics who have low folic acid levels face a greatly increased possibility of developing colon cancer.

Preparations

To correct a folic acid deficiency, supplements are taken in addition to food. Since the functioning of the B vitamins is interrelated, it is generally recommended that the appropriate dose of B-complex vitamins be taken in place of single B vitamin supplements. The Recommended Dietary Allowances (RDA) for folate is 400 mcg per day for adults, 600 mcg per day for pregnant women, and 500 mcg for nursing women. Medicinal dosages of up to 1,000–2,000 mcg per day may be prescribed.

Precautions

Folic acid is not stable. It is easily destroyed by exposure to light, air, water, and cooking. Therefore, the supplement should be stored in a dark container in a cold, dry place, such as a refrigerator. Many medications interfere with the body's absorption and use of folic acid. This includes sulfa drugs, sleeping pills, estrogen, anti-convulsants, birth control pills, **antacids**, quinine, and some **antibiotics**. Using large

WWW.BOOKBAZ.IR

KEY TERMS

Homocysteine—An amino acid involved in the breakdown and absorption of protein in the body.

Preeclampsia—A serious disorder of late pregnancy in which the blood pressure rises, there is a large amount of retained fluids, and the kidneys become less effective and excrete proteins directly into the urine.

Raynaud's disease—A symptom of various underlying conditions affecting blood circulation in the fingers and toes and causing them to be sensitive to cold.

Recommended Dietary Allowance (RDA)—Guidelines for the amounts of vitamins and minerals necessary for proper health and nutrition established by the National Academy of Sciences in 1989.

Water-soluble vitamins—Vitamins that are not stored in the body and are easily excreted. They must, therefore, be consumed regularly as foods or supplements to maintain health.

amounts of folic acid (e.g., more than 5,000 mcg per day) can mask a vitamin B_{12} deficiency and thereby risk of irreversible nerve damage.

Side effects

At levels of 5,000 mcg or less, folic acid is generally safe for use. Side effects are uncommon. However, large doses may cause nausea, decreased appetite, bloating, gas, decreased ability to concentrate, and **insomnia**. Large doses may also decrease the effects of phenytoin (Dilantin), a seizure medication.

Interactions

As with all B-complex vitamins, it is best to take folic acid with the other B vitamins. Vitamin C is important to the absorption and functioning of folic acid in the body.

Patience Paradox

Folic acid deficiency anemia

Definition

Folic acid deficiency, an abnormally low level of one of the B **vitamins**, results in anemia characterized by red blood cells that are large in size but few in number.

Description

Folic acid is necessary for growth and cellular repair, since it is a critical component of DNA and RNA as well as essential for the formation and maturation of red blood cells. Folic acid deficiency is one of the most common of all vitamin deficiencies. Although it occurs in both males and females, folic acid deficiency anemia most often affects women over age 30. It becomes increasingly common as age impedes the body's ability to absorb folic acid, a water-soluble vitamin that is manufactured by intestinal bacteria and stored for a short time in the liver. Folic acid deficiency has also been implicated as a cause of neural tube defects in the developing fetus. Recent research has shown that adequate amounts of folic acid can prevent up to one-half of these **birth defects**, if women start taking folic acid supplements shortly before conception. Research from China in 2004 showed that women who were low in B vitamins and folate before conception, though not technically anemic, still had increased risk of lower birthweight babies and adverse **pregnancy** outcome.

A healthy adult needs at least 400 mcg of folic acid every day. Requirements at least double during pregnancy, and increase by 50% when a woman is **breastfeeding**. The average American diet, high in fats, sugar, and white flour, provides about 200 mcg of folic acid, approximately the amount needed to maintain tissue stores of the substance for six to nine months before a deficiency develops. Most of

the folic acid in foods (with the exception of the folic acid added to enriched flour and breakfast cereals) occurs as folate. Folate is only about pne-half as available for the body to use as is the folic acid in pills and supplements. Folate also is easily destroyed by sunlight, overcooking, or the storing of foods at room temperature for an extended period of time.

Good dietary sources of folate include:

- leafy green vegetables
- liver
- mushrooms
- oatmeal
- peanut butter
- red beans
- soy
- wheat germ

Causes and symptoms

This condition usually results from a diet lacking in foods with high folic acid content, or from the body's inability to digest foods or absorb foods having high folic acid content. Other factors that increase the risk of developing folic acid deficiency anemia are:

- age
- alcoholism
- birth control pills, anticonvulsant therapy, sulfa antibiotics, and certain other medications
- illness
- smoking
- stress

Fatigue is often the first sign of folic acid deficiency anemia. Other symptoms include:

- anorexia nervosa
- pale skin
- paranoia
- rapid heartbeat
- sore, inflamed tongue
- weakness
- weight loss

Diagnosis

Diagnostic procedures include blood tests to measure hemoglobin, an iron-containing compound that carries oxygen to cells throughout the body. Symptoms may be reevaluated after the patient has taken prescription folic acid supplements.

Treatment

Folic acid supplements are usually prescribed, and self-care includes avoiding:

- alcohol
- non-herbal tea, antacids, and phosphates (contained in beer, ice cream, and soft drinks), which restrict iron absorption
- tobacco

A person with folic acid deficiency anemia should rest as often as necessary until restored energy levels make it possible to resume regular activities. A doctor should be seen if **fever**, chills, muscle aches, or new symptoms develop during treatment, or if symptoms do not improve after two weeks of treatment.

Alternatives

Alternative therapies for folic acid deficiency anemia may include **reflexology** concentrated on areas that influence the liver and spleen. Increasing consumption of foods high in folate is helpful. Eating a mixture of yogurt (8 oz) and turmeric (1 tsp) also may help resolve symptoms. A physician should be contacted if the tongue becomes slick or smooth or the patient:

- bruises or tires easily
- feels ill for more than five days
- feels weak or out of breath
- looks pale or jaundiced

Prognosis

Although adequate folic acid intake usually cures this condition in about three weeks, folic acid deficiency anemia can make patients infertile or more susceptible to infection. Severe deficiencies can result in **congestive heart failure**.

Prevention

Eating raw or lightly cooked vegetables every day will help maintain normal folic acid levels, as will taking a folic acid supplement containing at least 400 mcg of this vitamin. Because folic acid deficiency can cause birth defects, all women of childbearing age who can become pregnant should consume at least 400 mcg of folic acid daily; a woman who is pregnant should have regular medical checkups, and take a good prenatal vitamin.

Follicle-stimulating hormone test

Definition

The follicle-stimulating hormone (FSH) test measures the amount of FSH in the blood. FSH is a hormone that regulates the growth and development of eggs and sperm, and this test is used to diagnose or evaluate disorders involving the pituitary gland and reproductive system.

KEY TERMS

Anovulatory bleeding—Bleeding without release of an egg from an ovary.

Hypopituitarism—Underactivity of the pituitary gland.

Hypothalamus—The part of the brain that controls the endocrine system.

Klinefelter's syndrome—Chromosomal abnormality characterized by small testes and male infertility.

Multiple endocrine neoplasia—Abnormal tissue growth on one or more of the endocrine (hormone-secreting) glands.

Polycystic ovary disease—A condition in which a woman has little or no menstruation, is infertile, has excessive body hair, and is obese. The ovaries may contain several cysts.

Turner syndrome—Chromosomal abnormality characterized by immature reproductive organs in women.

Purpose

FSH testing is performed if a physician suspects the patient may have a disorder involving the reproductive system or pituitary gland. The pituitary gland produces FSH, which stimulates the growth of the sacks (follicles) that surround the eggs in a woman's ovaries. This is important for the process of ovulation, in which the egg is released. In men, FSH stimulates production of sperm. If there are abnormal levels of FSH in the blood it may mean that one of several disorders are present. Normal fluctuations occur as a result of **puberty**, the menstrual cycle, **pregnancy**, and **menopause**.

The FSH test is performed more often on women than on men. In women, it is used to determine if menopause has begun, to diagnose **infertility** and **menstrual disorders** (such as anovulatory bleeding), to measure hormone levels in children who enter puberty at an early age, and to diagnose other disorders. In men, it can be used to determine early puberty, abnormal tissue growth on one or more of the hormone-secreting (endocrine) glands (called multiple endocrine neoplasia), or to diagnose other disorders.

Description

The FSH test is a blood test. Blood will be drawn from the patient and analyzed in a laboratory.

Preparation

In preparation for the test, there are no food or fluid intake restrictions. Patients may be advised to discontinue certain medications for 48 hours before the test. A menstruating woman having hot flashes or irregular periods should be tested on the second or third day of her menstrual cycle. A woman who has missed a period and is having other menopausal symptoms can be tested at any time.

Aftercare

No aftercare is necessary.

Risks

There are no risks associated with this test.

Results

Normal FSH test results vary according to age and sexual maturity. The phase of a woman's menstrual cycle or use of birth-control pills also affects test results.

For an adult male, normal results range from about 4–25 units of FSH in every liter of blood (U/L) or about 5–20 micro-international units in every milliliter.

For a premenopausal woman, normal values range from 4–30 U/L or 5–20 micro-international

units per milliliter. In a pregnant woman, FSH levels are too low to measure. After menopause, normal values range from 40–250 U/L or 50–100 micro-international units per milliliter.

FSH levels fluctuate during premenopause. If no other symptoms are present, an elevated FSH level should not be interpreted as proof that menopause has begun.

Abnormal

Anorexia nervosa and disorders of the hypothalamus or pituitary gland can result in abnormally low FSH levels.

Abnormal levels can also indicate:

- infertility
- hypopituitarism
- Klinefelter syndrome (in men)
- turner syndrome
- ovarian failure
- polycystic ovary syndrome

Follicular cysts *see* **Ovarian cysts**

Folliculitis

Definition

Folliculitis is inflammation or infection of one or more hair follicles (openings in the skin that enclose hair).

Description

Folliculitis can affect both women and men at any age. It can develop on any part of the body, but is most likely to occur on the scalp, face, or parts of the arms, armpits, or legs not usually covered by clothing.

Small, yellowish-white blister-like lumps (pustules) surrounded by narrow red rings are usually present with both bacterial folliculitis and fungal folliculitis. Hair can grow through or alongside of the pustules, which sometimes ooze blood-stained pus.

Acne folliculitis. *(Custom Medical Stock Photo, Inc.)*

Folliculitis can cause **boils** and, in rare instances, serious skin infections. Bacteria from folliculitis can enter the bloodstream and travel to other parts of the body.

Causes and symptoms

Folliculitis develops when bacteria, such as *Staphylococcus,* or a fungus enters the body through a cut, scrape, surgical incision, or other break in the skin near a hair follicle. Scratching the affected area can trap fungus or bacteria under the fingernails and spread the infection to hair follicles on other parts of the body.

The bacteria that cause folliculitis are contagious. A person who has folliculitis can infect others who live in the same household.

Factors that increase the risk of developing folliculitis include:

- dermatitis
- diabetes
- dirty, crowded living conditions
- eczema
- exposure to hot, humid temperatures
- infection in the nose or other recent illness
- tight clothing

WWW.BOOKBAZ.IR

Diagnosis

Diagnosis is based on the patient's medical history and observations. Laboratory analysis of the substance drained from a pustule can be used to distinguish bacterial folliculitis from fungal folliculitis.

Treatment

Bacterial folliculitis may disappear without treatment, but is likely to recur. Non-prescription **topical antibiotics** like Bacitracin, Mycitracin, or Neomycin, gently rubbed on to affected areas three or four times a day, can clear up a small number of bacterial folliculitis pustules. Oral **antibiotics** such as erythromycin (Erythocin) may be prescribed if the infection is widespread. The drug griseofulvin (Fulvicin) and topical antifungal medications are used to treat fungal folliculitis.

A doctor should be notified if:

- pustules spread after treatment has begun or reappear after treatment is completed
- the patient's fever climbs above 100°F (37.8°C)
- the patient develops boils or swollen ankles
- redness, swelling, warmth, or pain indicate that the infection has spread
- unexplained new symptoms appear

Alternatives

Eating a balanced diet, including protein, complex carbohydrates, healthy fats, fresh fruits and vegetables, and drinking eight to 10 glasses of water a day may stimulate the body's immune system and shorten the course of the infection. Garlic (*Allium sativum*) and goldenseal (*Hydrastis canadensis*), both antiseptic agents against staph infections, may be taken. The daily dosage would vary from person to person and is based on the severity of the infection. **Echinacea** (*Echinacea* spp.) is helpful in modulating immune function. Again, the dosage would vary.

Daily doses of 30–50 mg zinc and 1,000–5,000 mg Vitamin C (taken in equal amounts at several times during the day), and 300–2,000 mg bioflavinoids can also strengthen the body's infection-fighting ability. High doses of **vitamins** and **minerals** should not be used without a doctor's approval.

Prognosis

If properly treated, the symptoms of bacterial folliculitis generally disappear in about two weeks. Fungal folliculitis should clear up within six weeks. But it can worsen if the condition is misdiagnosed and inappropriately treated with steroid creams.

Prevention

Anyone who has a tendency to develop folliculitis should cleanse the skin with antibacterial soap twice a day and before shaving and should not use oily skin lotions. Men should not shave while the beard area is infected. When they begin shaving again, they should use a new blade each time. Women who have had fungal folliculitis should use depilatory creams instead of razors. Daily shampooing can help prevent folliculitis in the scalp. The spread of infection can be prevented by not sharing towels or washcloths.

Food allergies

Definition

Food **allergies** are the body's abnormal response to specific proteins found in food. These proteins normally are harmless but cause a reaction in some people. They can occur when food is either eaten or touched.

Demographics

About one-quarter of American households have a member with a food allergy. However, this statistic is derived from self-reported information rather than rigorous studies. Many people use the term "food allergy" to describe what is actually a food intolerance. A food intolerance is a reaction to food that does not involve the immune system. **Lactose intolerance** is a common food intolerance, while **celiac disease** is a food allergy.

Eight foods cause 90% of all food allergies. These are:

- milk
- eggs
- peanuts

Common food allergies

The following food allergens are identified by the Food and Drug Administration (FDA) as the most common and must be clearly labeled on food packaging:

- Milk
- Eggs
- Peanuts
- Tree nuts (such as almonds, cashews, walnuts)
- Fish (such as bass, cod, flounder)
- Shellfish (such as crab, lobster, shrimp)
- Soy
- Wheat

SOURCE: Mayo Clinic, "Food allergies: Understanding food labels." Available online at: http://www.mayoclinic.org/diseases-conditions/food-allergy/in-depth/food-allergies/art-20045949?pg=1(accessed September 5, 2014).

(Table by PreMediaGlobal. Reproduced by permission of Gale, a part of Cengage Learning.)

- tree nuts (walnuts, cashews, pecans, almonds, etc.)
- fish
- shellfish
- soy
- wheat

Description

All food contains proteins that enter the body when the food is eaten, or in some cases if it is touched. Allergic reaction occurs when the body responds to these normally benign proteins as if they were harmful. The first time the food is consumed, the body reacts with an abnormal biological alarm. As the food is digested and broken down into proteins that enter the bloodstream, protective cells, called antibodies, are formed. Usually, antibodies are used to attack germs, such as bacteria or viruses, that invade the body. In this case, antibodies protect from disease by destroying the germs. Antibodies prompt other reactions in the body, such as a **fever** to kill disease cells or the dilating of blood cells so that blood can reach infected areas of the body more rapidly.

The second time the food is ingested, the antibodies alert the body that an invader is present, and the body mounts an attack. The body's response causes the symptoms of an allergic reaction.

Causes and symptoms

When the body encounters an allergen, it releases large amounts of a chemical called histamine. This release of histamine is responsible for allergic symptoms. Symptoms of food allergy can range from mildly annoying to dangerous and life threatening. These symptoms include:

- tingling of the mouth
- tingling or numbness in arms or legs
- skin rash or hives
- itching
- abdominal cramps
- vomiting
- diarrhea
- breathing difficulties
- sudden drop in blood pressure (hypotension)
- swelling of the tongue
- swelling of the face and throat
- loss of consciousness
- death

The most serious symptom of food allergy is **anaphylaxis**. Anaphylaxis, also called anaphylactic **shock**, is a sudden and potentially life threatening allergic reaction in which the whole body reacts to an allergen. During anaphylaxis, the airway constricts, making breathing difficult. Swelling of the throat may block airways as well. **Vomiting** and **diarrhea** may occur. The face may swell and the skin may become itchy with a rash or **hives**. The heart may race and the heartbeat may become irregular.

Diagnosis

The offending food must be identified if food allergy reactions are to be avoided. To identify food allergies, a doctor will first record the patient's detailed medical history. It is a good idea for patients to keep a food diary documenting all foods eaten and when, as well as any physical symptoms and when they occurred. In most cases, patterns of reactions to specific foods can be seen in the food diary.

Other means of diagnosing food allergies include:

- Blood tests (RAST, CAP–RAST). In a blood test, a sample of blood is drawn and antibodies in the blood are measured. These antibodies form in response to specific foods and occur only after the body has had an allergic reaction. An IgE test measures the level of Immunoglobulin E (IgE), which is specific for each food. Individual food allergies may be identified by this test.
- Skin tests. In a skin allergy test, a small amount of extract of a food that is suspected of causing an allergic reaction is placed on the skin. The skin is

WWW.BOOKBAZ.IR

then scratched in that area and observed for reaction. If an allergy exists, a small bump (similar to a mosquito bite) will appear, usually within 15 minutes. The skin test is a rapid way to see if a food allergy exists.

- Food challenge. This is a food test in which neither the testing doctor nor the patient knows what food is given. Opaque capsules are filled (by an assistant or another doctor) with foods that are suspected of causing allergies and foods that are not. The capsules prevent the patient from tasting or smelling the food. The patient swallows a capsule, and the doctor observes to see if a reaction occurs. This method of diagnosis is not appropriate for a person who has had a severe allergic reaction. It is time consuming and is usually performed when a doctor suspects the allergic reaction is not being caused by food. The test can rule out food as a cause for allergic reactions.
- Elimination diet. Similar to the food challenge, elimination diets help to determine which foods are responsible for allergy symptoms. All suspected foods are removed from the diet and then gradually added back in one at a time, to see which food item (if any) produces a response. Elimination diets may also discover food intolerances or sensitivities. They should not be used if the person has had a severe allergic reaction.

KEY TERMS

Allergen—A foreign substance that causes an allergic reaction in some sensitive people but not in most others.

Anaphylaxis—Also called anaphylactic shock; a severe allergic reaction characterized by airway constriction, tissue swelling, and lowered blood pressure.

Celiac disease—A chronic digestive disorder in which eating foods that contain the protein gluten (found in wheat flour, rye, and barley) causes an immune reaction that damages the small intestine and interferes with the absorption of food.

Elimination diet—A diet in which the patient excludes a specific food (or group of foods) for a period of time in order to determine whether the food is responsible for symptoms of an allergy or other disorder. Elimination diets are also known as food challenge diets.

Immunoglobulin (Ig)—Also called an antibody; a substance made by B cells that neutralizes specific disease-causing substances and organisms. Immunoglobulins are divided into five classes: IgA, IgD, IgE, IgG, and IgM.

Treatment

Treatment for an allergic reaction is administration of an antihistamine drug. The most common antihistamine is diphenhydramine hydrochloride, which is found in over-the-counter drugs, such as Benadryl, and in some prescription drugs. If taken immediately, **antihistamines** can stop or moderate an allergic reaction.

In cases of a severe allergy or anaphylaxis, an injection of a strong antihistamine called epinephrine (also known as adrenaline) may be used. An auto-injectable form of epinephrine (Epi-Pen) that looks similar to a large ballpoint pen can be carried at all times if a person has a history of severe allergy. If a severe allergic reaction occurs, the auto-injector is held against the skin and the medication is self-administered as a shot. Epinephrine is a strong antihistamine; it often can stop anaphylaxis symptoms.

Nutrition and dietary concerns

A doctor and nutritionist should be consulted if a food allergy is suspected. Removing foods from the diet can cause an unbalanced diet that may be deficient in necessary nutrients. Since some of the most common foods that cause allergies include milk, eggs, and wheat, significant sources of protein, **calcium**, and fiber may be removed. With the assistance of healthcare professionals, **diets** can be modified and healthy substitutions identified to avoid nutrient deficiencies.

Individuals following a special diet to treat other medical conditions should always consult a doctor before altering that diet. Eliminating foods from a medically prescribed diet may aggravate an existing health condition and could be harmful.

Prognosis

There is no cure for food allergies, but allergic reactions can be prevented by avoiding food(s) that cause an allergic response.

Prevention

It is essential that individuals with serious food allergies read the labels of every food they eat. A

federal law called the Food Allergen Labeling and Consumer Protection Act (FALPCA) took effect on January 1, 2006. This law mandates that all food containing milk, eggs, fish, crustacean shell fish, peanuts, tree nuts, wheat, or soy must note this on the label.

Ingredients that may cause allergies are listed on the label after the word "Contains." If these ingredients have names that are not readily known as versions of foods that may cause allergic reactions, the manufacturer will list the allergen in parentheses—for example, albumin (egg) or casein (milk). Additives for coloring or texture that may cause allergic reactions must also be listed.

Most individuals with food allergies are allergic to only one food; however, a peanut allergy may indicate reaction to tree nuts as well. Many manufacturers who process peanut products, process other nut products as well. Machines that handle and package these products may spread small pieces of peanut to other products. The FALPCA mandates that labels note this fact.

Food poisoning

Definition

Food poisoning—often called foodborne illness, disease, or infection—is illness caused by eating food or drinking water contaminated with disease-causing bacteria, viruses, parasites, or environmental toxins. Toxins may also be present within the food itself, such as the poisons in some mushrooms. Food **poisoning** is sometimes referred to as **gastroenteritis** or infectious **diarrhea**.

Description

Foodborne illness is a serious **public health** concern in the United States and around the world. More than 250 different foodborne diseases have been identified, primarily infections caused by pathogenic microorganisms. In 2011, the U.S. Centers for Disease Control and Prevention (CDC) reported that about 48 million Americans—one in six—suffer from food poisoning every year. Although unpleasant, most cases are not severe enough to require medical treatment. Nevertheless, food poisoning results in 128,000 hospitalizations and 3,000 deaths annually in the United States and is estimated to cost $3–6 billion annually in direct medical care and lost productivity. The very young, the elderly, pregnant women, and people with weakened immune systems—such as HIV/AIDS, leukemia, and transplant patients—are more likely to suffer severe food poisoning that results in hospitalization and life-threatening complications.

Disease-causing organisms and chemicals can contaminate food at any point in the food-production chain. The majority of food poisonings result from contamination with animal or human feces during slaughter, processing, transport, storage, or preparation. The U.S. Food and

WWW.BOOKBAZ.IR

Common pathogens causing food poisoning

Pathogen	Common host(s)
Campylobacter	Poultry
Clostridium botulinum	Home and improperly canned foods
Escherichia coli O157:H7 *(E. coli)*	Undercooked, contaminated ground beef
Listeria monocytogenes	Found in a variety of raw foods, such as uncooked meats and vegetables, and in processed foods that become contaminated after processing
Salmonella	Poultry, eggs, meat, and milk
Shigella	This bacteria is transmitted through direct contact with an infected person or from food or water that have become contaminated
Vibrio vulnificus	Contaminated seafood

(Table by PreMediaGlobal. © Cengage Learning®.)

Drug Administration (FDA) estimates that 90% of raw poultry sold at retail stores carries some disease-causing bacteria. Other raw meat products and eggs are contaminated to a lesser degree. Fruits and vegetables can also be contaminated in the field with feces or pesticides, as well as during harvesting, processing, distribution, and storage. Oysters and other filter-feeding shellfish can concentrate harmful bacteria that are normally present in seawater.

Although thorough cooking kills most bacteria, the CDC estimates that about 97% of food poisonings are due to improper food handling, such as undercooking or poor refrigeration, with 80% of such cases occurring in restaurants, cafeterias, or institutions such as nursing homes, schools, and prisons. The remaining 20% of cases come from improper food handling in the home.

Nevertheless, the U.S. food supply is probably the safest in the world, and serious outbreaks of food poisoning are relatively rare. Travel outside the United States, to countries with poorer sanitation, water purification, and food-handling practices, increases the risk of food poisoning. Bioterrorism experts are also concerned that disease-causing organisms could intentionally be introduced into the food or water supply to cause mass outbreaks of food poisoning.

Causes and symptoms

Food poisoning is primarily caused by a variety of different bacteria. According to the 2010 estimates, *Salmonella* infections accounted for the greatest number of hospitalizations (35%) and deaths (28%). In addition to *Salmonella*, other bacteria that commonly cause food poisoning include *Campylobacter*, *Toxoplasma*, *Escherichia coli* O157, *Listeria*, *Clostridium perfringens*, *Staphylococcus aureus*, *Shigella*, and *Clostridium botulinum*. Each has a slightly different incubation period and duration, but all except *C. botulinum* cause inflammation of the intestines and diarrhea. Food and water also can be contaminated by viruses (e.g., norovirus, **cholera**, rotavirus), environmental toxins (e.g., heavy metals), and poisons produced within the food itself (e.g., **mushroom poisoning**, shellfish poisoning).

BACTERIA. Bacterial contamination is the leading cause of food poisoning. At room temperature, bacteria reproduce at astounding rates. A single bacterium that divides every half hour can produce 17 million offspring in 12 hours. Bacteria fall into two general categories. One group causes symptoms of food poisoning by directly infecting the intestines causing irritation and diarrhea. The other group releases toxins (poisons) as they grow and reproduce. These toxins affect the digestive system and often cause **vomiting** first followed by diarrhea. Common bacteria include:

- Bacteria of the genus *Salmonella* are common in reptiles, birds, and mammals. They are found most often in eggs, poultry, dairy products, and beef. Infection with *Salmonella* causes nausea, vomiting, stomach cramps, headache, and low-grade fever. Symptoms begin anywhere from 6–48 hours after exposure and may last for seven days. In people with weakened immune systems, *Salmonella* infection can be life-threatening.
- Bacteria of the genus *Campylobacter* cause more diarrheal illnesses worldwide than any other group of bacteria. They produce fairly mild diarrhea, fever, and stomach cramps. *Campylobacter* bacteria are found in almost all raw chicken and turkey. Cross-contamination, that is putting cooked food down where raw food had been, is a leading cause of food poisoning from *Campylobacter*. These bacteria are also transmitted by water contaminated with animal feces.
- *Escherichia coli* are a large group of bacteria, only some of which cause food poisoning. *E. coli* food poisoning usually begins with watery diarrhea that later turns bloody. One strain of *E. coli* known as 0157:H7 is most often found in undercooked hamburger, but has also been found in ready-to-eat raw spinach. This particular strain can cause kidney failure and death, especially in children and the elderly.

ALICE CATHERINE EVANS (1881–1975)

(© Corbis.)

Alice Catherine Evans was born on January 29, 1881, in Neath, Pennsylvania. Evans was the second of two children born to Anne Evans and William Howell. Evans taught grade school for four years because she could not afford to pay college tuition, and at that time a college degree was not required to teach young children. Following her time as a teacher, Evans enrolled at the Cornell University College of Agriculture, earning her BS degree. Evans' professor recommended her for a scholarship, which she received, and she began her master's degree program at the University of Wisconsin from which she graduated in 1910.

In 1911, instead of continuing her education, Evans took a position with the University of Wisconsin's Dairy Division as a researcher studying cheese making. In 1913, she moved to Washington, DC, with the division and worked with a team on identifying the cause of contamination in raw cow's milk. By 1917, Evans' research had shown that the bacteria responsible for undulant (Malta) fever was similar to one found when a cow experienced a spontaneous abortion. When administered to guinea pigs, the two bacteria produced similar results. Her findings were met with much skepticism but, as time went on, Evans' research began to gain support. She continued to document cases of the disease and to argue for the pasteurization process. Finally, after 1930, officials responsible for public health and safety realized the need for this process, which ultimately became a standard procedure. Evans retired from her position with the National Institute of Health in 1945 and died on September 5, 1975.

- *Clostridium botulinum* is a bacteria that causes the disease botulism. *C. botulinum* produces a toxin that affects the nervous system and can cause difficulty breathing and paralysis. Symptoms do not appear until one to four days after exposure. Botulism is associated with improperly canned food (often home canned products), smoked fish, and honey. Infection with *C. botulinum* is uncommon but serious and often fatal. Proper cooking kills this bacterium.
- *Shigella* is a common cause of diarrhea in travelers to developing countries. It is associated with contaminated food and water, crowded living conditions, and poor sanitation. The bacterial toxins affect the small intestine. The disease runs its course in two to three days. Dehydration is a common complication. Most people recover on their own, although they may feel exhausted. Children who are malnourished or have weakened immune systems may die.
- *Staphylococcus aureus* is found in dust, air, and sewage. The bacteria are spread primarily by food handlers using poor sanitary practices. Almost any food can be contaminated, but salad dressings, milk products, cream pastries, and any food kept at room temperature, rather than hot or cold, are likely candidates. It is difficult to estimate the number of cases of food poisoning from *Staphylococcus aureus* that occur each year, because its symptoms are so similar to those caused by other foodborne bacteria. Many cases are mild and the victim never sees a doctor.
- *Listeria monocytogenes* is a ubiquitous bacterium in soil, groundwater, plants, and animals that causes listeriosis.

VIRUSES. A large group of viruses called **noroviruses** are an extremely common cause of foodborne illness. In recent years, these viruses have caused major outbreaks of gastrointestinal disease on cruise ships and in nursing homes. They cause more vomiting than diarrhea than any other viruses. Unlike many of the other causes of food poisoning, these viruses are not usually naturally present in food. They are usually transferred from the hands of infected food handlers to the food that they are preparing, especially to foods such as salads and sandwiches.

WWW.BOOKBAZ.IR

Rotavirus infection is the leading cause of severe diarrhea in infants and children. Two vaccines that prevent most **rotavirus infections** are available for infants in the United States. One vaccine requires two doses, the other three. The first dose must be given after age six weeks and before age 15 weeks. In countries where a rotavirus vaccine is available, the number of cases of serious diarrhea and death from **dehydration** in infants has decreased substantially. This virus still remains a major killer of infants in underdeveloped countries.

PARASITES. Parasites that cause food poisoning usually come from contaminated water. They often cause mild symptoms that are slow to develop but last for several weeks. *Giardia* causes watery diarrhea and is often acquired by drinking untreated water from lakes or streams. *Cryptosporidium* is a parasite that causes large amounts of watery diarrhea for three to four days. Healthy people usually recover quickly, but in people with weakened immune systems, symptoms can persist for a long time. *Toxoplasma gondii* is a parasite that is responsible for 24% of food-poisoning deaths from identified agents.

NATURAL TOXINS. Natural poisons found in some wild mushrooms can cause anything from **nausea and vomiting** to **hallucinations**, **coma**, and death, depending on the amount and species of mushroom eaten. Mushroom poisoning is a medical emergency. People who believe they have eaten a poisonous mushroom should, if possible, take a sample of the mushroom or their vomit to the emergency room with them. Identifying the type of mushroom causing the illness can help determine the most effective treatment.

Oysters, clams, mollusks, and scallops can contain toxins that affect the nervous system. Symptoms usually begin with a tingling in the mouth, then the arms and legs. Individuals may become dizzy and may have difficulty breathing. Shellfish poisoning is a medical emergency because the muscles needed for breathing may become paralyzed. Similar symptoms result from eating the Japanese puffer fish which contains a natural poison that in its skin and digestive system that affects the nervous system.

MAN-MADE TOXINS. Man-made toxins include all pesticides, fertilizers, disinfectants, and any other chemicals remaining in food when it is eaten that can cause illness. Contamination is accidental, and often the result of ignorance or a misunderstanding of how to apply the chemical. Symptoms may develop rapidly or slowly depending on the type of chemical and the amount of exposure. Chemical poisoning requires prompt medical evaluation.

Other food-poisoning agents include toxins in poisonous mushrooms and reef fish, food contaminated with pesticides or herbicides, and certain communicable pathogens that are occasionally foodborne. The latter include the *Shigella* family of bacteria, **hepatitis A** virus, rotavirus, and the parasites *Giardia lamblia* and *Cryptosporidium*.

Ingested pathogens adhere to the intestinal lining and begin to multiply. Some types remain in the intestine and produce toxins that enter the bloodstream. Other pathogens invade deeper body tissues.

Emerging agents

The agents responsible for food poisoning evolve over time and require constant surveillance. Whereas **typhoid fever**, **tuberculosis**, and cholera were once common foodborne illnesses, improved food safety—including milk pasteurization, safer canning methods, and water treatment—have overcome these diseases in the developed world. However other sources of food poisoning have emerged. For example, in 1991, the parasite *Cyclospora* contaminated Guatemalan raspberries. In 1998, a new strain of the bacterium *Vibrio parahaemolyticus* contaminated oyster beds in Galveston Bay.

Some foodborne bacterial infections appear to be on the increase. In 2011, at least 29 people died and at least 139 people across 28 states were sickened from eating cantaloupe contaminated with *L. monocytogenes* and traced to unsanitary conditions and poor handling at a single Colorado farm. Both **listeriosis** and salmonellosis can be transmitted to a fetus, causing **miscarriage**, fetal or newborn death, premature delivery, or severe illness in mother and infant. Since most listeriosis outbreaks are caused by contaminated animal products, pregnant women are often advised to avoid deli meats.

Complications of some foodborne infections are now being recognized as the cause of certain serious medical conditions. For example, *Campylobacter* can cause Guillain-Barré syndrome and *E. coli* O157:H7 and related bacteria can cause hemolytic uremic syndrome (HUS), the most common cause of **acute kidney failure** in children.

Sources of contamination

Contamination can occur at any point in the food-production chain:

- in the field, by application of illegal or higher-than-approved pesticides or herbicides
- during processing, by improper handling of raw materials, contaminated water, inadequate disinfection, inadequate timing or temperature, or contamination with pest-control poisons
- during storage and transportation, by improper temperatures, inappropriate use of fumigants, inadequate sanitization of food-carrying tanker trucks, or contamination with insects or rodent droppings
- in stores and restaurants, with improper temperatures, cross-contamination between raw and cooked foods, improper disinfection of food-preparation surfaces, improper hand washing, or transmission by infected food handlers
- at home, by leaving food at room temperature, inadequate cooking, cross-contamination between raw and cooked foods, or failure to properly reheat leftovers

Raw or undercooked meat, poultry, eggs, fish—especially filter-feeding shellfish such as oysters, clams, scallops, and mussels—and raw (unpasteurized) milk are common sources of food poisoning. Raw fruits and vegetables may have been exposed to fresh manure or contaminated water, and washing will reduce but not eliminate pathogens. Misidentified wild mushrooms, improperly canned foods, luncheon and deli meats, and soft cheeses, such as brie and feta, are also associated with food poisoning.

Processed foods that pool ingredients from multiple sources are particularly dangerous, since a pathogen from one animal can contaminate an entire batch. For example, a single hamburger can include meat from hundreds of animals, a glass of raw milk may be the pooled milk of hundreds of cows, unpasteurized fruit juice can be made from many individual fruits, and a restaurant omelet can contain eggs from hundreds of chickens. An estimated one in every 20,000 eggs is contaminated with *Salmonella*. Egg-containing products, such as mayonnaise or raw cookie dough, also carry a risk.

Small numbers of bacteria in foods can multiply quickly under warm, moist conditions. A few bacteria in alfalfa or bean seeds can multiply to contaminate an entire batch of sprouts. Refrigeration or freezing generally prevents bacteria from multiplying. However *L. monocytogenes* and the foodborne bacterium *Yersinia enterocolitica* can grow and multiply at refrigerator temperatures. High levels of salt, sugar, or acid prevent bacteria from growing in preserved foods.

Symptoms

Food poisoning symptoms usually develop suddenly, within one to 48 hours after eating contaminated food, and resolve within one to a few days. Symptoms and their severity depend on the causative agent, the amount ingested, and the health of the individual; however food-poisoning symptoms tend to be similar, regardless of their cause:

- watery and sometimes bloody diarrhea
- nausea followed by forceful vomiting
- painful abdominal cramps
- fever
- headache
- dizziness
- blurred vision
- difficulty breathing

Children commonly vomit everything in their stomachs for three or four hours, followed by mild or moderate vomiting. Severe vomiting, especially in combination with diarrhea, can cause dehydration—the excessive loss of body fluids. Young children can become dehydrated very quickly.

Chemical food poisoning is a medical emergency. Natural poisons found in some wild mushrooms can cause, in addition to nausea and vomiting, hallucinations, coma, and death. Shellfish toxins and Japanese puffer fish poison affect the nervous system, beginning with tingling in the mouth, arms, and legs, followed by **dizziness** and possibly difficulty breathing. Poisoning with man-made toxic chemicals varies with the type of chemical and degree of exposure.

Diagnosis

In healthy people, food poisoning by a pathogen is usually a mild, short-lived illness that does not require specific diagnosis or medical treatment. Most mild food poisoning is diagnosed by the symptoms of vomiting, diarrhea, and stomach cramps coupled with information about what the individual has recently eaten. The length of time between eating the suspect food and the start of symptoms gives physicians a clue about what particular organism may be causing the food poisoning. Blood and urine tests may be ordered to determine the individual's degree of dehydration and electrolyte (chemical) imbalances. In most cases, determining the exact pathogen that is causing the food poisoning is relatively unimportant, as treatment tends to be the similar for most causes. However, if

WWW.BOOKBAZ.IR

diarrhea is persistent, a **stool culture** may be done to provide more specific information.

Food poisoning can have serious complications in the very young, the elderly, and immunocompromised patients, and so it is sometimes necessary to identify the causative agent to begin appropriate treatment. The symptoms and length of time between consuming a suspected food and the onset of illness may suggest the culprit. However, unless the illness is part a known outbreak, laboratory tests may be required:

- Viral infections are usually identified by testing stool samples for genetic markers of a specific virus. However tests for noroviruses are not widely available, so this most common form of food poisoning is rarely diagnosed.
- Bacteria such as *Salmonella*, *Campylobacter*, and *E. coli* O157:H7 are usually identified from cultured stool samples. However, it is estimated that only one in 30 cases of salmonellosis is confirmed by a laboratory test. The CDC recommends that clinical laboratories test for both Shiga toxin and *E. coli* O157:H7 in the stools of all patients with community-acquired diarrhea or suspected HUS.
- Parasites are identified by examining stool samples under a microscope.
- Blood and urine tests can determine the extent of dehydration and electrolyte imbalances stemming from diarrhea and vomiting.

Treatment for poisoning from a natural or man-made toxin may require precise identification of the chemical. With suspected mushroom poisoning, a sample of the mushroom or the patient's vomit should be brought to the emergency department, if possible. In other cases, extensive blood tests are required or the stomach may be pumped and its contents tested. Sometimes **activated charcoal** is used to help absorb the poison in the stomach.

Treatment

Treatment for food poisoning usually involves preventing dehydration by replacing fluids and electrolytes lost through vomiting and diarrhea. Food poisoning can cause huge amounts of water and electrolytes to be lost very quickly, especially in infants and young children. The loss of 10–15% of body fluid is very serious and the loss of 20% is fatal. Severe dehydration may require hospitalization and intravenous fluids. Drugs are sometimes prescribed to stop persistent vomiting. Vomiting and diarrhea in infants and young children require especially prompt professional treatment because small children can become dehydrated within hours.

Mild cases of food poisoning can usually be treated at home, especially if there is no **fever**. Dehydration can be prevented or treated with over-the-counter (OTC) oral-rehydration solutions such as Ceralyte, Pedialyte, or Oralyte. These are available in supermarkets and pharmacies without a prescription. An electrolyte-replacement fluid can be made at home with one teaspoon of salt and four teaspoons of sugar per quart of water. Small sips should be given to young children as soon as vomiting and diarrhea begin. Children may continue to vomit and have diarrhea, but some of the fluid will be absorbed. In the past, parents were told to withhold solid food from children who had diarrhea. New research indicates that it is better for children to be allowed to eat solid food should they want it, even though diarrhea continues.

Adults and older children with food poisoning should avoid drinking coffee, tea, and soft drinks, especially soft drinks that contain **caffeine**, as these liquids promote dehydration. Sports drinks, such as Gatorade, do not replace losses properly and should not be used to treat diarrheal illnesses. Over-the-counter medications to stop or slow diarrhea such as Kaopectate, Pepto-Bismol, or Imodium will not shorten the duration of the disease, but may give the individual some control over his or her bowels. Consult a physician before giving these over-the-counter medicines to children. They should not be used in the presence of high fever or blood in the stool.

Individuals of all ages who are seriously dehydrated need to be treated promptly by a medical professional. In the case of severe dehydration, the individual may be hospitalized and fluids given intravenously (IV; directly into the vein). Drugs may also be prescribed to stop persistent vomiting. Although bacteria cause many cases of food poisoning, **antibiotics** are not routinely used in treatment. Some studies have shown that antibiotics are necessary only in about 10% of cases.

Botulism is treated in a different way from other food poisonings. Botulism antitoxin is given to adults, but not infants, if it can be administered within 72 hours after symptoms are first observed. If given later, it provides no benefit. Both infants and adults require hospitalization, often in the intensive care unit. If the ability to breathe is impaired, patients are put on a mechanical ventilator to assist their breathing and are fed intravenously until the **paralysis** passes.

Individuals who think their food poisoning symptoms may be caused by chemicals or natural toxins

should always seek emergency medical care immediately. These types of food poisoning are too serious to try to treat at home.

Although the food in the United States is very safe, occasionally major outbreaks of food poisoning occur that can be traced to a breakdown in the food handling system. Larger outbreaks can be identified and traced to their source because each state has a list of diseases that health professionals are required to report to the county public health service once positive diagnosis is made. Most states require that doctors and hospitals report confirmed cases of disease caused by *Salmonella* and *E. coli* 0157:H7 and several other food poisoning pathogens. This information is then passed on to the CDC.

Alternatives

Alternative practitioners offer the same advice as traditional practitioners concerning diet modification. In addition, they recommend taking charcoal tablets, *Lactobacillus acidophilus*, *Lactobacillus bulgaricus*, and citrus seed extract. An electrolyte replacement fluid can be made at home by adding one teaspoon of salt and four teaspoons of sugar to one quart of water. For food poisoning other than botulism, two homeopathic remedies, either *Arsenicum album* or *Nux vomica*, are strongly recommended.

In a recent review by the Cochrane Collaboration of 63 studies involving a total of 8,000 people, **probiotics** seems to be able to shorten the duration of diarrhea by 25 hours as compared with no treatment at all.

Prognosis

Most people have unpleasant gastrointestinal symptoms—vomiting and diarrhea—for a few days and then recover fully from food poisoning. In young children, dehydration is always a cause for concern. Worldwide, dehydration from diarrhea is the biggest killer of children under age 5. If dehydration can be controlled in young children with food poisoning, most recover with few complications. However, *E. coli* 0157:H7 can cause fatal renal failure in 3%–5% of children. This bacteria is most often acquired by eating unpasteurized apple cider or apple juice, alfalfa or bean sprouts.

Botulism is the deadliest of the bacterial foodborne illnesses. With prompt medical care, the death rate is less than 10%.

More serious long-term health problems often result from chemical poisonings. Toxins found in some wild mushrooms and some fish can cause permanent liver damage requiring a liver transplant or death. Pesticides and other chemical contamination can cause liver damage, kidney failure, and nervous system complications. In 2007, chemical contamination of pet food caused the death of hundreds of dogs and cats in the United States.

Prevention

Healthcare professionals and individuals should report foodborne illnesses to their local health departments so that outbreaks can be detected, traced, and halted. However, most food poisonings are preventable by appropriate handling and processing at each level of the food-production chain. **Breastfeeding** is the best way to protect infants from food poisoning.

Growers should apply only approved pesticides and herbicides at no higher than recommended levels. Processors must use clean sources of water to wash produce, regularly disinfect processing machinery, and use only safe pesticides.

Proper refrigeration is required in stores, restaurants, and homes. Food should not be held under warming lights or at room temperature for long periods; they should be kept at above 140°F (60°C) or below 40°F (4°C). Fresh foods and leftovers should be promptly refrigerated or frozen. Frozen food should be defrosted in the refrigerator or microwave, rather than at room temperature, and cooked immediately. Food that has been at room temperature for two to four hours should be discarded. Large quantities of food should be divided into shallow containers to cool more rapidly.

Hands should be washed thoroughly with soap and water before, during, and after preparing food and after using the bathroom or changing diapers. Anyone with a diarrheal illness should not prepare food for others. Food preparation surfaces and utensils should be washed frequently during food handling. Produce should be washed thoroughly before and again after peeling to prevent salmonellosis. The outer leaves of lettuce and cabbage should be discarded. Cross-contamination of foods can be avoided by never placing cooked food on plates or surfaces that previously held raw food.

Heating food to an internal temperature of 160°F (78°C), for even a few seconds, kills most bacteria, viruses, and parasites. *Clostridium* produces heat-resistant spores that must be destroyed with temperatures above boiling. Food thermometers should be used to check the internal temperature of cooked meat. Egg yolks should be cooked until firm. Bacterial toxins vary in their heat sensitivity. Although botulism

WWW.BOOKBAZ.IR

KEY TERMS

Botulism—Life-threatening paralytic food poisoning caused by botulinum toxin from the bacterium *Clostridium botulinum*.

Campylobacter—A genus of bacteria that can cause food poisoning and are found in almost all raw poultry.

Clostridium perfringens—A bacterium that is a common cause of food poisoning.

Dehydration—The abnormal depletion of body fluids, as from vomiting and diarrhea.

Diuretic—Medication that increases the urine output of the body.

Electrolytes—Ions—such as sodium, potassium, calcium, magnesium, chloride, phosphate, bicarbonate, and sulfate—that are dissolved in bodily fluids and regulate or affect most metabolic processes.

Gastroenteritis—Inflammation of the lining of the stomach and intestines.

Hemolytic uremic syndrome (HUS)—Kidney failure, usually in infants and young children, that can be caused by food poisoning with bacteria such as *Escherichia coli* or *Shigella*.

Lactobacillus acidophilus—This bacterium is found in yogurt and changes the balance of the bacteria in the intestine in a beneficial way.

Listeriosis—A usually mild illness caused by food poisoning with *Listeria monocytogenes*, but which can be serious or fatal in newborns, the elderly, and the immunocompromised and which can cause miscarriage, stillbirth, or premature birth if contracted during pregnancy.

Norovirus—Norwalk virus; a large family of RNA viruses that is the most common cause of food poisoning.

Salmonellosis—Food poisoning by bacteria of the genus *Salmonella*, which usually causes severe diarrhea and may be transmitted to the fetus.

Shiga toxin-producing *E. coli* (STEC)—Strains of the common, normally harmless, intestinal bacteria *Escherichia coli* that produce Shiga toxin, causing serious food poisoning; *E. coli* O157:H7 is the most commonly identified STEC in North America.

Staphylococcus aureus—A bacterium that causes food poisoning.

Toxoplasma gondii—A very common parasite that can cause toxoplasmosis and is a leading cause of death from food poisoning; although it infects large numbers of people, *T. gondii* is usually dangerous only in immunocompromised patients and in newly infected pregnant women.

toxin is completely inactivated by boiling, staphylococcal toxin is not. Milk, juice, and cider should be pasteurized. Irradiation of meat and other foods also destroys contaminating microbes.

Foot acupressure *see* **Reflexology**

Foot care

Definition

Foot care involves all aspects of preventative and corrective care of the foot and ankle. Doctors specializing in foot care are called podiatrists.

Purpose

During an average lifetime, each person walks about 115,000 miles and three-quarters of people have foot problems at some point in their lives.

Foot problems can arise from wearing ill-fitting shoes, from general wear and tear, as a result of injury, or as a complication of disease. People with **diabetes mellitus** or circulatory diseases are 20 times more likely to have foot problems than the general public.

Podiatrists are doctors who specialize in treating the foot and ankle. Other doctors who have experience with foot problems are family physicians, orthopedists, sports medicine specialists, and those who care for diabetics. Problems with the feet include foot **pain**, joint inflammation, plantar **warts**, **fungal infections** (like athlete's foot), nerve disorders, torn ligaments, broken bones, bacterial infections, and tissue injuries (like frostbite).

Precautions

People with diabetes or circulatory disorders should be alert to even small foot problems. In these people, a break in the skin can lead to infection, **gangrene**, and **amputation**.

Description

Daily foot care for people likely to develop foot problems includes washing the feet in tepid water with mild soap and oiling the feet with vegetable oil or a lanolin-based lotion. Toenails should be cut straight across above the level of the skin after soaking the feet in tepid water. **Corns and calluses** should not be cut. If they need removal, it should be done under the care of a doctor. Athletes foot and plantar warts should also be treated by a doctor if they develop in high risk patients.

Many people with diabetes or circulatory disorders have problems with cold feet. These problems can be reduced by avoiding **smoking** tobacco (smoking constricts the blood vessels), wearing warm socks, not crossing the legs while sitting or not sitting in one position too long, or avoiding constricting stockings.

People with circulatory problems should not use heating pads or hot water bottles on their feet, as even moderate heat can damage the skin if circulation is impaired.

Preparation

No special preparation other than an understanding of the nature of foot problems is necessary to begin routine foot care.

Aftercare

Foot care is preventative and should be ongoing throughout a person's life.

WWW.BOOKBAZ.IR

Risks

There are no risks associated with foot care. The risks are in ignoring the feet and allowing problems to develop.

Results

With regular care, foot disorders such as infections, skin **ulcers**, and gangrene can be prevented.

Foreign bodies *see* **Foreign objects**

Foreign objects

Definition

Foreign means "originating elsewhere" or simply "outside the body." Foreign objects, also known as foreign bodies, typically become lodged in the eyes, ears, nose, airways, and rectum of human beings.

Demographics

Swallowing foreign bodies is a fairly common pediatric emergency; about 80,000 cases involving persons 19 years old or younger are reported each year to the 67 poison control centers in the United States. In a recent survey of the parents of 1,500 children, 4% reported that their children had swallowed a foreign object of some kind. The highest incidence of swallowed foreign bodies is in children between the ages of six months and four years.

The type of object most frequently swallowed varies somewhat across different historical periods and cultures. A recent study comparing the Jackson collection of foreign bodies removed from children between 1920 and 1932 with data collected from North American children's hospitals between 1988 and 2000 found that coins have replaced safety pins as the objects most commonly swallowed by American children. In Asia, fish bones are a frequent offender because fish is a dietary staple in most countries of the Far East.

X ray of swallowed spoon and blade in the intestine. *(Photo Researchers, Inc.)*

In younger children, boys are at slightly greater risk than girls (53–47%) of swallowing foreign objects. Among teenagers, males are at a much higher risk than females of swallowing foreign bodies or inserting them into the rectum.

Younger children usually swallow or insert foreign objects into their bodies accidentally, usually as a result of play or exploring their environment. Adolescents are more likely to swallow or insert foreign bodies intentionally as a risk-taking behavior, a bid for attention, or while under the influence of drugs or alcohol. A small minority of teenagers who harm themselves by swallowing or inserting foreign bodies have **schizophrenia** or another psychotic disorder.

Description

Both children and adults experience problems caused by foreign objects getting stuck in their bodies. Young children are naturally curious and

may intentionally put shiny objects, such as coins or button batteries, into their mouths. They also like to stick things in their ears and up their noses. Adults may accidentally swallow a non-food object or inhale a foreign body that gets stuck in the throat. Even if an object like a toothpick successfully passes through the esophagus and into the stomach, it can get stuck inside the rectum. Airborne particles can lodge in the eyes of people at any age.

Foreign bodies can be in hollow organs (like swallowed batteries) or in tissues (like bullets). They can be inert or irritating. If they irritate, they will cause inflammation and scarring. They can bring infection with them or acquire it and protect it from the body's immune defenses. They can obstruct passageways either by their size or by the scarring they cause. Some can be toxic.

Causes and symptoms

Eyes

Dust, dirt, sand, or other airborne material can lodge in the eyes, causing minor irritation and redness. More serious damage can be caused by hard or sharp objects that penetrate the surface and become embedded in the cornea or conjunctiva (the mucous membranes around the inner surface of the eyelids). Swelling, redness, bleeding from the surface blood vessels, sensitivity to light, and sudden vision problems are all symptoms of foreign matter in the eyes.

Ears and nose

Children will sometimes put things into their noses, ears, and other openings. Beans, popcorn kernels, raisins, and beads are just a few of the many items that have been found in these bodily cavities. On occasion, insects may fly into the ears and nose. **Pain**, **hearing loss**, and a sense of something stuck in the ear are symptoms of foreign bodies in the ears. A smelly, bloody discharge from one nostril is a symptom of foreign bodies in the nose.

Airways and stomach

At a certain age children will eat anything. A very partial list of items recovered from young stomachs includes: coins, chicken bones, fish bones, beads, rocks, plastic toys, pins, keys, round stones, marbles, nails, rings, batteries, ball bearings, screws, staples, washers, a heart pendant, a clothespin spring, and a toy soldier. Some of these items pass right on through and come out the other end. The progress of metal objects has been successfully followed with a metal detector. Others, like sharp bones, can get stuck and cause trouble. Batteries are corrosive and must be removed immediately.

Some objects can be inhaled unintentionally. The most commonly inhaled item is probably a peanut. A crayon and a cockroach have been found in a child's windpipes. These items always cause symptoms (difficulty swallowing and spitting up saliva, for instance) and may elude detection for some time while the child is being treated for **asthma** or recurring **pneumonia**.

Adults are not exempt from unusual inedibles. Dental devices are commonly swallowed. Adults with mental illness or subversive motives may swallow inappropriate objects, such as toothbrushes.

Rectum

Sometimes a foreign object will successfully pass through the throat and stomach only to get stuck at the juncture between the rectum and the anal canal. Items may also be self-introduced to enhance sexual stimulation and then get stuck. Sudden sharp pain during elimination may signify that an object is lodged in the rectum. Other symptoms vary depending upon the size of the object, its location, how long it has been in place, and whether or not infection has set in.

Diagnosis

The symptoms are as diverse as the objects and their locations. The most common manifestation of a foreign object anywhere in the body is infection. Even if the object started out sterile, germs may still be introduced. Blockage of passageways—breathing, digestive or excretory—is another result. Pain is common.

Treatment

Eyes

Small particles like sand may be removable without medical help, but if the object is not visible or cannot be retrieved, prompt emergency treatment is necessary. **Trauma** to the eyes can lead to loss of vision. Before attempting any treatment, the person should move to a well-lit area where the object can be better viewed. Hands should be washed and only clean, preferably sterile, materials should make contact with the eyes. If the particle is small, it may be dislodged by blinking or pulling the upper lid over the

WWW.BOOKBAZ.IR

lower lid and flushing out the speck. A clean cloth can also be used to remove the particle. Once the object is removed, the eye should be rinsed with clean, lukewarm water or an opthalmic wash.

If the foreign object cannot be removed at home, the eye should be lightly covered with sterile gauze to discourage rubbing. A physician will use a strong light and possibly special eye drops to locate the object. Surgical tweezers can effectively remove many objects. An antibiotic sterile ointment and a patch may be prescribed. If the foreign body has penetrated the deeper layers of the eye, an ophthalmic surgeon will be consulted for emergency treatment.

Ears and nose

A number of ingenious extraction methods have been devised for removing foreign objects from the nose and ears. A bead in a nostril, for example, can be popped out by blowing into the mouth while holding the other nostril closed. Insects can be floated out of the ear by pouring warm (not hot) mineral oil, olive oil, or baby oil into the ear canal. Items that are lodged deep in the ear canal are more difficult to remove because of the possibility of damaging the ear drum. These require emergency treatment from a qualified physician.

Airways and stomach

Mechanical obstruction of the airways, which commonly occurs when food gets lodged in the throat, can be treated by applying the **Heimlich maneuver**. If the object is lodged lower in the airway, a bronchoscope (a special instrument to view the airway and remove obstructions) can be inserted. If the object is blocking the entrance to the stomach, a fiberoptic endoscope (an illuminated instrument that views the interior of a body cavity) may be used. The physician typically administers a sedative and anesthetizes the throat. The foreign object will then either be pulled out or pushed into the stomach, depending on whether or not the physician thinks it will pass through the digestive tract on its own. Objects in the digestive tract that are not irritating, sharp, or large may be followed as they continue on through. Sterile objects that are not causing symptoms may be left in place. Surgical removal of the offending object is necessary if it is causing symptoms.

Rectum

A rectal retractor can remove objects that a physician can feel during **physical examination**. Surgery may be required for objects deeply lodged within the recturm.

KEY TERMS

Bronchoscope—An illuminated instrument that is inserted into the airway to inspect and retrieve objects from the bronchial tubes.

Conjunctiva—Mucous membranes around the inner surface of the eyelid.

Cornea—The rounded, transparent portion of the eye that covers the pupil and iris and lets light into the interior

Endoscopy—The surgical use of long, thin instruments that have both viewing and operating capabilities.

Heimlich maneuver—An emergency procedure for removing a foreign object lodged in the airway that is preventing the person from breathing.

Prevention

Using common sense and following safety precautions are the best ways to prevent foreign objects from entering the body. Parents and other child care providers should toddler-proof their homes. Batteries should be stored in a locked cabinet and properly disposed of after use. To minimize the chance of youngsters inhaling food, parents should not allow children to eat while walking or playing. Adults should chew food thoroughly and not talk while chewing. Many eye injuries can be prevented by wearing safety glasses while using tools

Forensic medicine

Definition

Forensic medicine—sometimes called medical jurisprudence—is the branch of medicine that deals with the application of medical information and expertise to matters of civil or criminal law. Forensic medicine is also considered a branch of forensic science, which includes disciplines outside medicine (such as archaeology, art history, criminalistics, document analysis, and others) that may be involved in legal cases. The English word *forensic* comes from a Latin word that means "before the forum," because ancient Roman law required criminal cases to be brought before a group of citizens in the Roman Forum (Forum Romanum), which still stands in the heart of present-day Rome.

Description

Forensic medicine in the West first emerged during the seventeenth century in the form of surgeons and physicians being called as expert witnesses in legal proceedings. The first book on the subject, Paolo Zecchia's *Quaestiones medico-legales*, published in 1621, dealt with such questions as distinguishing between accidental death and homicide, or between a **stillbirth** and infanticide. Zecchia also raised questions that are still relevant to forensic medicine, such as deciding which methods of examination yield reliable knowledge and what qualifications should be expected of a medical witness in a court of law.

The nineteenth century saw several advances in forensic medicine, such as the development of toxicology from organic chemistry; the emergence of psychiatry as a tool in evaluating a defendant's competency to stand trial; and the publication of the first handbook of criminal investigation in 1893, written by an Austrian jurist named Hans Gross. The first department of forensic medicine in the United States was not established until 1933, when such a department was set up at New York University (NYU). The medical examiners of the City of New York were then given faculty appointments in the department. In 1968 the Institute of Forensic Medicine of New York University and the City of New York was created; in 1977 it

A pathologist preparing to perform an autopsy examination. *(Mauro Fermariello / Science Source)*

WWW.BOOKBAZ.IR

was named after Dr. Milton Helpern, Chief Medical Examiner from 1954 to 1973. The Institute presently includes the Office of the Chief Medical Examiner of the City of New York (OCME); NYU School of Medicine, and NYU College of Dentistry.

The various branches of forensic medicine were not, however, recognized as specialties until the early twentieth century. Physicians and surgeons were called to give expert testimony as local courts saw fit, but so-called medical examiners (MEs) were not required to have any medical training. Some parts of the United States used persons called coroners to certify deaths within their jurisdictions and to order investigations when necessary, but these coroners were public officials who were not required to be licensed physicians. This situation persists in the United States as of 2014; a map of the current hodgepodge of medical examiner/coroner systems can be viewed on the National Library of Medicine website at http://www.nlm.nih.gov/visibleproofs/exhibition/III_B_316.pdf. The first school of forensic science was not established until 1909, when Archibald Reiss founded the Institut de police scientifique at the University of Lausanne in Switzerland. It is now known as the École des sciences criminelles (ESC).

Contemporary forensic medicine is not only divided into distinct specialties, however, but is increasingly distinguished from laboratory analysis of crime scene evidence and what the Federal Bureau of Investigation (FBI) calls support specialties (research and development, evidence response teams, hazmat response teams, and others). At present the major specialties within forensic medicine include:

- Forensic pathology: Forensic pathology is a subspecialty of medical pathology. A forensic pathologist in the United States is a physician who has completed a residency in anatomical pathology, an examination for board certification in pathology, and a specialized fellowship in forensic pathology. Forensic pathologists perform autopsies, in which they determine the cause of death (blood loss, disease process, heart attack, etc.) and the manner of death (homicide, suicide, accidental, natural, or undetermined). They also document the location and size of wounds, scar tissue, tattoos, and other distinctive marks or features on the body.
- Forensic odontology: Forensic odontology is a subspecialty of dentistry. Forensic odontologists use their understanding of the anatomy and development of human teeth to evaluate the age, sex, or nutritional status of unidentified human remains; to confirm a person's identity on the basis of past dental records; and to examine bite marks on the victim or on objects found at a crime scene as evidence of the perpetrator's identity.
- Forensic psychiatry and behavioral science: Forensic psychiatrists are frequently called as expert witnesses in regard to two major concerns in criminal law: the defendant's competency to stand trial (CST); and the defendant's mental state at the time of the offense; i.e. did the accused know what he/she was doing at the time the crime was committed and know that the act was wrong? Forensic psychiatrists may also be involved in the care of prisoners with mental illnesses as well as the care of persons in mental hospitals who have committed violent crimes.
- Forensic toxicology: Forensic toxicology studies the use and effect of poisonous materials on the human body. It involves the disciplines of pharmacology, analytical chemistry, and clinical chemistry. Forensic toxicologists typically examine samples of blood, urine, fecal matter, hair, stomach contents, or tissues from the brain, liver, or spleen to determine the role of drugs or other chemicals in the person's death. The two most recent techniques used in forensic toxicology are gas chromatography, a technique that allows the separation and analysis of substances that can be vaporized; and mass spectrometry, which helps to identify the amount and type of chemicals within a sample.
- Forensic anthropology: Forensic anthropology uses information gained from human biology and physical anthropology to identify bodies that are badly decomposed, burned, partially scattered by animals, or otherwise unrecognizable. It is also used to help determine the cause of death and/or the sex, weight, height, age, and ethnicity of the remains. Forensic anthropology has been used to solve questions of the identity of the remains of historical figures, such as the recent case of Richard III (1452–1485), the last English king of the Plantagenet dynasty. The king's remains were discovered beneath a city parking lot in 2012 and confirmed to be Richard's in February 2013.
- Forensic entomology: Forensic entomology is the examination of the effects of insects and other arthropods (centipedes, millipedes, and crustaceans) on the human body after death. The species of insect found on a body and its stage of development can assist in determining the time of death and in some cases, the location where the crime was committed. A new subfield of forensic entomology is entomotoxicology, in which the insects found on a decomposed human body can be tested for drugs or other toxins to determine whether the substances were present in the human body at the time of death. A chart outlining

the various specialties and subspecialties in forensic science, forensic medicine, and criminalistics can be viewed on the NLM website at http://www.nlm.nih.gov/visibleproofs/exhibition/III_A_109.pdf.

Purpose

The basic purpose of forensic medicine is to assist the civil and criminal justice systems by evaluating medical, dental, or psychiatric evidence for presentation in a court of law according to accepted standards of scientific observation and measurement. It may also be used to research new techniques or advances in technology to improve detection and analysis of human remains, human behavior, and other evidence relevant to death investigations.

Forensic medicine is also often involved in identifying the victims of mass fatalities (natural disasters, transportation disasters, terrorist attacks, industrial explosions, etc.) even when criminal investigations are not required.

Preparation

Preparation for work in forensic medicine involves at the minimum several years of study after college. Forensic pathologists and psychiatrists in the United States are doctors of medicine (MDs) or doctors of osteopathic medicine (DOs) who have completed four years (five years for Canadian psychiatrists) of residency in pathology or psychiatry plus one or two years of specialized fellowships in forensic pathology or psychiatry. Forensic toxicologists are either physicians or pharmacologists (PharmDs) with specialized training in forensic toxicology. Forensic odontologists are dentists holding either the DDS or DMD degree who have completed graduate work in forensic odontology. Forensic anthropologists and forensic entomologists typically hold PhD degrees in physical anthropology or biology.

The field of forensic medicine also includes technicians, laboratory assistants, and field workers who assist with investigations, courtroom presentations, and research who hold bachelor's or master's degrees in one of the health professions or an area of forensic science. Forensic pathologists, for example, are often assisted by morgue technicians known as dieners in the United States. Dieners are responsible for handling and cleaning the corpse, and in some jurisdictions may be allowed to perform a complete dissection during an **autopsy**. The École des sciences criminelles of the University of Lausanne offers a bachelor's degree in forensic science and several master's degrees in forensic toxicology, criminalistics, criminology, and the legal aspects of forensic science. In the United States, there are a number of undergraduate institutions that offer courses in forensic science, but only about ten that offer full undergraduate majors in the field. One of the better-known undergraduate programs in forensic science is that offered by the Pennsylvania State University, which also offers a master's degree in the field.

KEY TERMS

Autopsy—A thorough examination of a human body after death to determine the cause and manner of death and to evaluate any disease or injury that may be present. It is also known as a postmortem examination or necropsy.

Coroner—A public officer who determines (in some cases with the help of a jury) the cause of any death not obviously due to natural causes; certifies the death for the public record; and may proceed with an investigation. The name comes from the Latin word for crown, because the English coroner was originally an officer of the Crown.

Criminalistics—A general term for various analytical techniques used in crime investigations, such as fingerprint and trace evidence analysis, tire track and footprint analysis, ballistics, toolmark examination, and others.

Diener—In the United States, a morgue technician or attendant who assists a forensic pathologist during an autopsy.

Medical examiner (ME)—A public officer charged with the duty of investigating deaths or injuries that occur under suspicious circumstances and to perform postmortem examinations. In most jurisdictions in the United States, the ME is required to hold a medical degree (MD or DO), but in some areas, he or she need not have any special medical or scientific training.

Risks

Most risks in the field of forensic medicine concern unintentional exposure to toxic substances or pathogenic organisms in the laboratory, during an autopsy, or at the scene of a mass disaster. There have been some incidents of forensic psychiatrists being attacked by defendants or prisoners during a mental health evaluation.

WWW.BOOKBAZ.IR

The other major risk concerns the ongoing need to revise the techniques used in forensic medicine in light of new discoveries and technological advances. Forensic psychiatry in particular is still somewhat controversial because the categories used in psychiatric evaluations do not fit neatly into the categories of guilt or innocence required in a court of law. Another emerging issue in forensic medicine is the role of social media in influencing the shape and speed of forensic investigations.

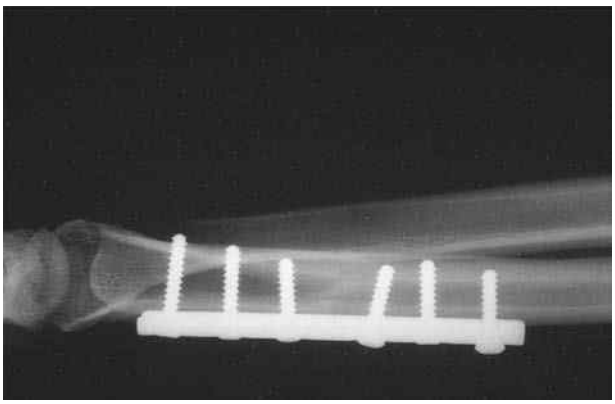
Fracture repair

Definition

Bone is the hardest tissue in the human body, but when bones are subjected to forces that exceed their strength, they may break. The likelihood that a bone will break depends on the location of the bone in the body, the thickness of the bone, and the circumstances under which the force was applied. The most commonly broken bones are those in the wrist, hip, and ankle. The terms "break" and "fracture" mean the



An x-ray image of a healing fracture. *(Custom Medical Stock Photo, Inc.)*

same thing. Fracture repair is the process of rejoining and realigning the ends of broken bones. It usually performed by an orthopedist, general surgeon, or family doctor. In cases of an emergency, **first aid** measures should be used to provide temporary realignment and **immobilization** until proper medical help is available.

Purpose

Fracture repair is required when there is a need to restore the normal alignment and function of a broken bone. Throughout the stages of fracture healing, the bones must be held firmly in the correct position. In the event that a fracture is not properly repaired, misalignment of the bone may occur, resulting in possible physical dysfunction of the bone, adjacent joint, or region of the body.

Demographics

The incidence of **fractures** that occur in the United States can only be estimated because fractures are not always reported. The average person sustains two to three fractured bones during the course of a lifetime. A reasonable estimate is approximately nine million fractures per year.

Fractures are slightly more common in children and adolescents than in young adults due to the levels and kinds of activities in which they engage. Fractures become more common in adults as they age due to changes in bone structure and generally diminished levels of physical activity.

Description

Fracture repair is usually performed by an orthopedic surgeon, general surgeon, or family physician. In cases of an emergency, first aid measures should be used for temporary realignment and immobilization until proper medical help can be obtained. Relatively uncomplicated fractures may be immobilized in a physician's office. More commonly, fractures are treated in a hospital setting.

Fracture repair is accomplished by means of applied **traction**, surgery, and immobilizing affected bones. The bone fragments are aligned as closely as possible to their normal position without injuring the skin. Metal wires or screws may be needed to align smaller bone fragments. Once the broken ends of the bone are set, the affected area is immobilized for several weeks and kept rigid with a sling, plaster cast, brace, or splint. With the use of traction, muscles pulling on the fracture site are neutralized by weights attached to a series of ropes running over pulleys. Strategically implanted electrical stimulation devices have proven beneficial in healing a fracture site, especially when the fracture is healing poorly and repair by other means is difficult.

Preparation

Preparation often begins with emergency splinting to immobilize the body part or parts involved. When fracture repair is necessary, the procedure is often performed in a hospital, but can also be successfully done in an outpatient surgical facility, doctor's office, or emergency room. Before any surgery for fracture repair, blood and urine studies may be performed, and x rays may be obtained. It must be noted, however, that not all fractures are immediately apparent on an initial x-ray examination. In such a case, when a fracture is highly suspected, the extent of the fracture can be properly diagnosed by repeating the x rays 10–14 days later. Depending upon the situation, local or general **anesthesia** may be used during fracture repair.

Aftercare

Immediately following surgical repair of a fracture, x rays may be taken again through the cast or splint to evaluate whether the rejoined pieces are in a good position for healing. The x ray can also be performed before the application of the splint or cast. Persons need to **exercise** caution and not place excess pressure on any part of the cast until it is completely dry. Excess pressure on the operative site should also be avoided until complete healing has taken place and the injury has been re-examined by the physician or surgeon. If the cast becomes exposed to moisture, it may soften and require repair. For this reason, plastic has largely replaced plaster as the casting material of choice. The injured region should be elevated or

WWW.BOOKBAZ.IR

KEY TERMS

Compound fracture—A fracture in which the broken end or ends of the bone have penetrated through the skin; also known as an open fracture.

Staphylococcal infection—An infection caused by any of several pathogenic species of *Staphylococcus,* commonly characterized by the formation of abscesses in the skin or other organs.

Streptococcal infection—An infection caused by a pathogenic bacterium of one of several species of the genus *Streptococcus* or their toxins. Almost any organ in the body may be involved.

propped up whenever possible to reduce the possibility of swelling.

Risks

Surgical risks of fracture repair are greater in persons over 60 years of age because the bones often require more time to properly heal. **Obesity** may place extra stress on the fracture site, affecting healing and possibly increasing the risk of re-fracturing the same bone. The healing process after fracture repair may also be slowed by **smoking**, poor **nutrition**, **alcoholism**, and chronic illness. Some medications may affect the fracture site, causing poor union; such medications include anti-hypertensive drugs and **steroids** such as cortisone.

Possible complications following fracture repair include excessive bleeding, improper fit of joined bone ends, pressure on nearby nerves, delayed healing, and a permanent incomplete healing (union) of the fracture. If there is a poor blood supply to the fractured site and one of the portions of broken bone is not adequately supplied with blood, the bony portion may die and healing of the fracture will not take place. This complication is called aseptic **necrosis**. In addition, poor immobilization of the fracture from improper casting that permits motion between the bone parts may prevent healing and repair of the bone, and result in possible deformity. Infection can also interfere with bone repair. This risk is greater in the case of a compound fracture (a bone fracture involving a portion of bone that breaks through the surface of skin). Compound fracture sites provide ideal conditions for severe infections by *Streptococcus* and *Staphylococcus* bacteria. Occasionally, fractured bones in the elderly may never heal properly. The risk is increased when nutrition is poor.

Results

Once the procedure for fracture repair is completed, the body begins to produce new tissue to bridge the fracture site and rejoin the broken pieces. At first, this tissue (called a callus) is soft and easily injured. Later, the body deposits bone **minerals** (primarily compounds containing **calcium**) until the callus becomes a solid piece of bone. The fracture site is thus further strengthened with extra bone. It usually takes about six weeks for the pieces of a broken bone to knit (heal) together. The exact time required for healing depends on the type of fracture and the extent of damage. Before the use of x rays, fracture repair was not always accurate and frequently resulted in crippling deformities. With modern x-ray technology, physicians can view the extent of the fracture, check the setting following the repair, and be certain after the procedure that the bones have not moved from their intended alignment. Children's bones usually heal more rapidly than do the bones of adults.

Fractures

Definition

A fracture is a complete or incomplete break in a bone resulting from the application of excessive force.

Description

A fracture usually results from traumatic injury to bones causing the continuity of bone tissues or bony cartilage to be disrupted or broken. Fracture classifications include simple, compound, incomplete and complete. Simple fractures (more recently called "closed") are not obvious as the skin has not been ruptured and remains intact. Compound fractures (now commonly called "open") break the skin, exposing bone and causing additional soft tissue injury and possible infection. A single fracture means that one fracture only has occurred and multiple fractures refer to more than one fracture occurring in the same bone. Fractures are termed complete if the break is completely through the bone and described as incomplete or "greenstick" if the fracture occurs partly across a bone shaft. This latter type of fracture is often the result of bending or crushing forces applied to a bone.

Fractures are also named according to the specific part of the bone involved and the nature of the break. Identification of a fracture line can further classify fractures. Types include linear, oblique, transverse, longitudinal, and spiral fractures. Fractures can be further subdivided by the positions of bony fragments and are described as comminuted, non-displaced, impacted, overriding, angulated, displaced, avulsed, and segmental. Additionally, an injury may be classified as a fracture-dislocation when a fracture involves the bony structures of any joint with associated dislocation of the same joint.

Fractures line identification

Linear fractures have a break that runs parallel to the bone's main axis or in the direction of the bone's shaft. For example, a linear fracture of the arm bone could extend the entire length of the bone. Oblique and transverse fractures differ in that an oblique fracture crosses a bone at approximately a 45° angle to the bone's axis. In contrast, a transverse fracture crosses a bone's axis at a 90° angle. A longitudinal fracture is similar to a linear fracture. Its fracture line extends along the shaft but is more irregular in shape and does not run parallel to the bone's axis. Spiral fractures are described as crossing a bone at an oblique angle, creating a spiral pattern. This break usually occurs in the long bones of the body such as the upper arm bone (humerus) or the thigh bone (femur).

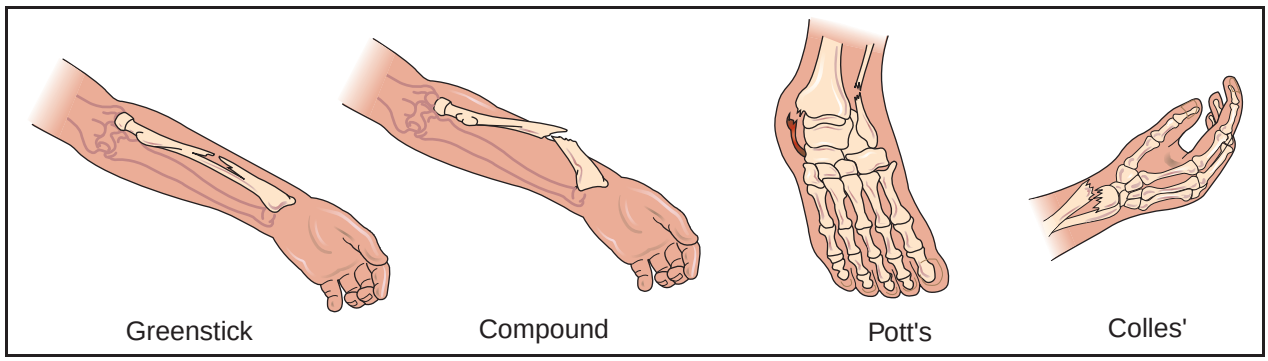
Bony fragment position identification

Comminuted fractures have two or more fragments broken into small pieces, in addition to the upper and lower halves of a fractured bone. Fragments of bone that maintain their normal alignment following a fracture are described as being non-displaced. An impacted fracture is characterized as a bone fragment forced into or onto another fragment resulting from a compressive force. Overriding is a term used to describe bony fragments that overlap and shorten the total length of a bone. Angulated fragments result in pieces of bone being at angles to each other. A displaced bony fragment occurs from disruption of normal bone alignment with deformity of these segments separate from one another. An avulsed fragment occurs when bone fragments are pulled from their normal position by forceful muscle contractions or resistance from ligaments. Segmental fragmented positioning occurs if fractures in two adjacent areas occur, leaving an isolated central segment. An example of segmental alignment is when the arm bone fractures in two separate places, with displacement of the middle section of bone.

Causes and symptoms

Individuals with high activity levels appear to be at greater risk for fractures. This group includes children and athletes participating in contact sports. Because of an increase in bone brittleness with **aging**, elderly persons are also included in this high-risk

WWW.BOOKBAZ.IR



Fractures usually result from a traumatic injury to a bone where the continuity of bone tissues or bony cartilage is disrupted or broken. The illustrations above feature common sites where fractures occur. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

population. Up to the age of 50, more men suffer from fractures than women due to occupational hazards. However, after the age of 50, women are more prone to fractures than men. Specific diseases causing an increased risk for fractures include Paget's disease, **rickets**, **osteogenesis imperfecta**, **osteoporosis**, **bone cancer** and tumors, and prolonged disuse of a non-functional body part such as after a **stroke**.

Symptoms of fractures usually begin with **pain** that increases with attempted movement or use of the area and swelling at the involved site. The skin in the area may be pale and an obvious deformity may be present. In more severe cases, there may be a loss of pulse below the fracture site, such as in the extremities, accompanied by numbness, tingling, or **paralysis** below the fracture. An open or compound fracture is often accompanied by bleeding or bruising. If the lower limbs or pelvis are fractured, pain and resistance to movement usually accompany the injury causing difficulty with weight bearing.

Diagnosis

Diagnosis begins immediately with an individual's own observation of symptoms. A thorough medical history and physical exam by a physician often reveals the presence of a fracture. An x ray of the injured area is the most common test used to determine the presence of a bone fracture. Any x-ray series performed involves at least two views of the area to confirm the presence of the fracture because not all fractures are apparent on a single x ray. Some fractures are often difficult to see and may require several views at different angles to see clear fracture lines. In some cases, CT, MRI or other imaging tests are required to demonstrate fracture. Sometimes, especially with children, the initial x ray may not show any fractures but repeat seven to 14 days later may show changes in the bone(s) of the affected area. If a fracture is open and occurs in conjunction with soft tissue injury, further laboratory studies are often conducted to determine if blood loss has occurred.

In the event of exercise-related stress fractures (micro-fractures due to excessive stress), a tuning fork can provide a simple, inexpensive test. The tuning fork is a metal instrument with a stem and two prongs that vibrate when struck. If an individual has increased pain when the tuning fork is placed on a bone, such as the tibia or shinbone, the likelihood of a stress fracture is high. Bone scans also are helpful in detecting stress fractures. In this diagnostic procedure, a radioactive tracer is injected into the bloodstream and images are taken of specific areas or the entire skeleton by CT or MRI.

Treatment

Treatment depends on the type of fracture, its severity, the individual's age and general health. The first priority in treating any fracture is to address the entire medical status of the patient. Medical personnel are trained not allow a painful, deformed limb to distract them from potentially life-threatening injury elsewhere or **shock**. If an open fracture is accompanied by serious soft tissue injury, it may be necessary to control bleeding and the shock that can accompany loss of blood.

First aid is the appropriate initial treatment in emergency situations. It includes proper splinting, control of blood loss, and monitoring vital signs such as breathing and circulation.

Immobilization

Immobilization of a fracture site can be done internally or externally. The primary goal of immobilization is to maintain the realignment of a bone long

ANTONIUS MATHIJSEN AND THE INVENTION OF PLASTER OF PARIS CASTS

(racornShutterstockcom)

Antonius Mathijsen (1805–1878), the inventor of plaster of Paris casts, was born in a small town in Holland. He was the son of a physician and had seven brothers and two sisters. Interest in medicine ran in the family, with Mathijsen and three of his brothers following in their father's footsteps and becoming physicians.

By the nineteenth century, it had long been accepted that the best regimen for healing broken bones was to immobilize the bone and ensure that patients got adequate rest. The methods of immobilization varied from culture to culture but generally involved wooden splints put around the limb. The limb was then wrapped with cloth or linen bandages to hold the splints in place. In most cases, the splints were bulky and prevented patients from moving freely. Some patients had to remain in bed for months.

By the early 1800s, broken legs and arms were being treated by creating a wooden box around the limb. The box was then filled with plaster of Paris or another substance that would harden over time, immobilizing the limb. Plaster of Paris is manufactured by heating gypsum (calcium sulfate dihydrate) until most of the water evaporates leaving a powdery substance. It was originally manufactured from gypsum mined near Paris, France. The box method of immobilization created problems, including little or no airflow to the limb, and a cast so heavy the patient was often unable to leave the bed at all.

Antonius Mathijsen was serving as a military surgeon in the Dutch army during the Crimean War (1853–1856) when he set out to find a better method for immobilizing broken bones. He developed six requirements for such a system: It had to (1) be easy and quick to apply, (2) harden quickly, (3) harden in such a way that a doctor could still access the injury to treat it as necessary, (4) be able to be formed to the shape and size of the limb being treated, (5) not be damaged by moisture from humidity or pus, and (6) be light enough to wear and inexpensive to create.

Mathijsen developed a method for creating a cast in which he took dry plaster of Paris and applied it to strips of cotton or linen bandage. The bandages containing the plaster of Paris were then wrapped around the broken limb. When the plaster of Paris was dampened, it quickly hardened into a single, solid mass, effectively immobilizing the limb.

This new technique was a significant improvement over previous methods and met all of Mathijsen's requirements. He first published a monograph about his new method in May 1852. The method quickly became the standard for treating broken limbs. The basic method was still used in the early 2000s, although the plaster of Paris is often replaced with other materials such as fiberglass.

enough for healing to start and progress. Immobilization by external fixation uses splints, casts, or braces. This may be the primary and only procedure for fracture treatment. Splinting to immobilize a fracture can be done with or without **traction**. In emergency situations if the injured individual must be moved by someone other than a trained medical person, splinting is a useful form of fracture management. It should be done without causing additional pain and without moving the bone segments. In a clinical environment, plaster of Paris casts are used for immobilization. Braces are useful as they often allow movement above and below a fracture site. Treatments for stress fractures include rest and decreasing or stopping any activity that causes or increases pain.

Fracture reduction

Fracture reduction is the procedure by which a fractured bone is realigned in normal position. It can be either closed or open. Closed reduction refers to realigning bones without breaking the skin. It is performed with manual manipulation and/or traction and is commonly done with some kind of anesthetic.

WWW.BOOKBAZ.IR

KEY TERMS

Avulsion fracture—A fracture caused by the tearing away of a fragment of bone where a strong ligament or tendon attachment forcibly pulls the fragment away from the bone tissue.

Axis—A line that passes through the center of the body or body part.

Comminuted fracture—A fracture where there are several breaks in a bone creating numerous fragments.

Compartment syndrome—Compartment syndrome is a condition in which a muscle swells but is constricted by the connective tissue around it, which cuts off blood supply to the muscle.

Contrast hydrotherapy—A series of hot and cold water applications. A hot compress (as hot as an individual can tolerate) is applied for three minutes followed by an ice cold compress for 30 seconds. These applications are repeated three times each and ending with the cold compress.

Osteogenesis imperfecta—A genetic disorder involving defective development of connective tissues, characterized by brittle and fragile bones that are easily fractured by the slightest trauma.

Osteoporosis—Literally meaning "porous bones," this condition occurs when bones lose an excessive amount of their protein and mineral content, particularly calcium. Over time, bone mass and strength are reduced leading to increased risk of fractures.

Paget's disease—Chromic disorder of unknown cause, usually affecting middle aged and elderly people, characterized by enlarged and deformed bones. Excessive breakdown and formation of bone tissue occurs with Paget's disease and can cause bone to weaken, resulting in bone pain, arthritis, deformities, and fractures.

Reduction—The restoration of a body part to its original position after displacement, such as the reduction of a fractured bone by bringing ends or fragments back into original alignment. The useof local or general anesthesia usually accompanies a fracture reduction. If performed by outside manipulation only, the reduction is described as closed; if surgery is necessary, it is described as open.

Rickets—A condition caused by the dietary deficiency of vitamin D, calcium, and usually phosphorus, seen primarily in infancy and childhood, and characterized by abnormal bone formation.

Traction—The process of placing a bone, limb, or group of muscles under tension by applying weights and pulleys. The goal is to realign or immobilize the part or to relieve pressure on that particular area to promote healing and restore function.

Open reduction primarily refers to surgery that is performed to realign bones or fragments. Fractures with little or no displacement may not require any form of reduction.

Traction is used to help reposition a broken bone. It works by applying pressure to restore proper alignment. The traction device immobilizes the area and maintains realignment as the bone heals. A fractured bone is immobilized by applying opposing force at both ends of the injured area, using an equal amount of traction and countertraction. Weights provide the traction pull needed or the pull is achieved by positioning the individual's body weight appropriately. Traction is a form of closed reduction and is sometimes used as an alternative to surgery. Since it restricts movement of the affected limb or body part, it may confine a person to bed rest for an extended period of time.

A person may need open reduction if there is an open, severe, or comminuted fracture. This procedure allows a physician to examine and surgically correct associated soft tissue damage while reducing the fracture and, if necessary, applying internal or external devices. Internal fixation involves the use of metallic devices inserted into or through bone to hold the fracture in a set position and alignment while it heals. Devices include plates, nails, screws, and rods. When healing is complete, the surgeon may or may not remove these devices. Virtually any hip fracture requires open reduction and internal fixation so that the bone will be able to support the patient's weight.

Alternatives

In addition to the importance of **calcium** for strong bones, many alternative treatment approaches recommend use of mineral supplements to help build and maintain a healthy, resilient skeleton. Some physical therapists use electro-stimulation over a fractured site to promote and expedite healing. Chinese traditional medicine may be helpful by working to reconnect chi through the meridian lines along the line of a

fracture. Homeopathy can enhance the body's healing process. Two particularly useful homeopathic remedies are *Arnica* (*Arnica montana*) and *Symphytum* (*Symphytum officinalis*). If possible, applying contrast **hydrotherapy** to an extremity (e.g., a hand or foot) of a fractured area can assist healing by enhancing circulation.

Prognosis

Fractures involving joint surfaces almost always lead to some degree of arthritis of the joint. Fractures can normally be cured with proper first aid and appropriate aftercare. If determined necessary by a physician, the fractured site should be manipulated, realigned, and immobilized as soon as possible. Realignment has been shown to be much more difficult after six hours. Healing time varies from person to person with the elderly generally needing more time to heal completely. A non-union fracture may result when a fracture does not heal, such as in the case of an elderly person or an individual with medical complications. Recovery is complete when there is no bone motion at the fracture site, and x rays indicate complete healing. Open fractures may lead to bone infections, which delay the healing process. Another possible complication is **compartment syndrome**, a painful condition resulting from the expansion of enclosed tissue and that may occur when a body part is immobilized in a cast.

Prevention

Adequate calcium intake is necessary for strong bones and can help decrease the risk of fractures. People who do not get enough calcium in their **diets** can take a calcium supplement. **Exercise** can help strengthen bones by increasing bone density, thereby decreasing the risk of fractures from falls. A University of Southern California study reported that older people who exercised one or more hours per day had approximately half the incidence of hip fractures as those who exercised fewer than 30 minutes per day or not at all.

Fractures can be prevented if safety measures are taken seriously. These measures include using seat belts in cars and encouraging children to wear protective sports gear. Estrogen replacement for women past the age of 50 has been shown to help prevent osteoporosis and the fractures that may result from this condition. In one study, elderly women on estrogen replacement therapy demonstrated the lowest occurrence of hip fractures when compared to similar women not on estrogen replacement therapy.

Fragile X syndrome

Definition

Fragile X syndrome is the most common form of inherited intellectual disabilities (ID). Individuals with this condition have developmental delay, variable levels of ID, and behavioral and emotional difficulties. They may also have characteristic physical traits. Generally, males are affected with moderate ID and females with mild ID.

WWW.BOOKBAZ.IR

Description

Fragile X syndrome is also known as Martin-Bell syndrome, Marker X syndrome, and FRAXA syndrome. It is caused by a mutation in the FMR-1 gene, located on the X chromosome. The role of the gene is unclear, but it is probably important in early development.

In order to understand fragile X syndrome it is important to understand how human genes and chromosomes influence this condition. Normally, each cell in the body contains 46 chromosomes (23 pairs). These chromosomes consist of genetic material (DNA) needed for the production of proteins, which lead to growth, development, and physical/intellectual characteristics. The first 22 pairs of chromosomes are the same in males and females. The remaining two chromosomes are called the sex chromosomes (X and Y). The sex chromosomes determine whether a person is male or female. Males have only one X chromosome, which is inherited from the mother at conception, and they receive a Y chromosome from the father. Females inherit two X chromosomes, one from each parent. Fragile X syndrome is caused by a mutation in a gene called FMR-1. This gene is located on the X chromosome. The FMR-1 gene is thought to play an important role in the development of the brain, but the exact way that the gene acts in the body is not fully understood.

Fragile X syndrome affects males and females of all ethnic groups. It is estimated that about one in 4,000-6,250 males are affected with fragile X syndrome. There are approximately one-half as many females with fragile X syndrome as there are males. The carrier frequency in unaffected females is one in 100–600, with one study finding a carrier frequency of one in 250.

Causes and symptoms

For reasons not fully understood, the CGG sequence in the FMR-1 gene can expand to contain between 54 and 230 repeats. This stage of expansion is called a premutation. People who carry a premutation do not usually have symptoms of fragile X syndrome, although there have been reports of individuals with a premutation and subtle intellectual or behavioral symptoms. Individuals who carry a fragile X premutation are at risk to have children or grandchildren with the condition. Female premutation carriers may also be at increased risk for earlier onset of **menopause**; however, premutation carriers may exist through several generations of a family and no symptoms of fragile X syndrome will appear.

The size of the premutation can expand over succeeding generations. Once the size of the premutation exceeds 230 repeats, it becomes a full mutation and the FMR-1 gene is disabled. Individuals who carry the full mutation may have fragile X syndrome. Since the FMR-1 gene is located on the X chromosome, males are more likely to develop symptoms than females. This is because males have only one copy of the X chromosome. Males who inherit the full mutation are expected to have mental impairment. A female's normal X chromosome may compensate for her chromosome with the fragile X gene mutation. Females who inherit the full mutation have an approximately 50% risk of mental impairment. The phenomenon of an expanding trinucleotide repeat in successive generations is called anticipation. Another unique aspect of fragile X syndrome is that mosaicism is present in 15–20% those affected by the condition. Mosaicism is when there is the presence of cells of two different genetic materials in the same individual.

The mutation involves a short sequence of DNA in the FMR-1 gene. This sequence is designated CGG. Normally, the CGG sequence is repeated between six to 54 times. People who have repeats in this range do not have fragile X syndrome and are not at increased risk to have children with fragile X syndrome. Those affected by fragile X syndrome have expanded CGG repeats (more than 200) in the first exon of the FMR1 gene (the full mutation)

Fragile X syndrome is inherited in an X-linked dominant manner (characters are transmitted by genes on the X chromosome). When a man carries a premutation on his X chromosome, it tends to be stable and usually will not expand if he passes it on to his daughters (he passes his Y chromosome to his sons). Thus, all of his daughters will be premutation carriers like he is. When a woman carries a premutation, it is unstable and can expand as she passes it on to her children, therefore a man's grandchildren are at greater risk of developing the syndrome. There is a 50% risk for a premutation carrier female to transmit an abnormal mutation with each **pregnancy**. The likelihood for the premutation to expand is related to the number of repeats present; the higher the number of repeats, the greater the chance that the premutation will expand to a full mutation in the next generation. All mothers of a child with a full mutation are carriers of an FMR-1 gene expansion. Ninety-nine percent of patients with fragile X syndrome have a CGG expansion, and less than 1% have a point mutation or deletion on the FMR1 gene.

Individuals with fragile X syndrome appear normal at birth but their development is delayed. Most

boys with fragile X syndrome have mental impairment. The severity of mental impairment ranges from learning disabilities to severe ID. Behavioral problems include attention deficit and hyperactivity at a young age. Some may show aggressive behavior in adulthood. Short attention span, poor eye contact, delayed and disordered speech and language, emotional instability, and unusual hand mannerisms (hand flapping or hand biting) are also seen frequently. Characteristic physical traits appear later in childhood. These traits include a long and narrow face, prominent jaw, large ears, and enlarged testes. In females who carry a full mutation, the physical and behavioral features and intellectual disabilities tend to be less severe. About 50% of females who have a full mutation are intellectually disabled. Other behavioral characteristics include whirling, spinning, and occasionally **autism**.

Children with fragile X syndrome often have frequent ear and sinus infections. Nearsightedness and lazy eye are also common. Many babies with fragile X syndrome may have trouble with sucking and some experience digestive disorders that cause frequent gagging and **vomiting**. A small percentage of children with fragile X syndrome may experience seizures. Children with fragile X syndrome also tend to have loose joints which may result in joint **dislocations**. Some children develop a curvature in the spine, flat feet, and a heart condition known as **mitral valve prolapse**.

Diagnosis

Any child with signs of developmental delay of speech, language, or motor development with no known cause should be considered for fragile X testing, especially if there is a family history of the condition. Behavioral and developmental problems may indicate fragile X syndrome, particularly if there is a family history of ID. Definitive identification of the fragile X syndrome is made by means of a genetic test to assess the number of CGG sequence repeats in the FMR-1 gene. Individuals with the premutation or full mutation may be identified through **genetic testing**. Genetic testing for the fragile X mutation can be done on the developing baby before birth through **amniocentesis** or **chorionic villus sampling** (CVS), and is 99% effective in detecting the condition due to trinucleotide repeat expansion. Prenatal testing should only be undertaken after the fragile X carrier status of the parents has been confirmed and the couple has been counseled regarding the risks of recurrence. While prenatal testing is possible to do with CVS, the results can be difficult to interpret and additional testing may be required.

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

CGG or CGG sequence—Shorthand for the DNA sequence: cytosine-guanine-guanine. Cytosine and guanine are two of the four molecules, otherwise called nucleic acids, that make up DNA.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother's vagina or abdominal wall and a sample of cells is collected from around the early embryo. These cells are then tested for chromosome abnormalities or other genetic diseases.

Chromosome—A microscopic thread-like structure found within each cell of the body that consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

FMR-1 gene—A gene found on the X chromosome. Its exact purpose is unknown, but it is suspected that the gene plays a role in brain development.

Mitral valve prolapse—A heart defect in which one of the valves of the heart (which normally controls blood flow) becomes floppy. Mitral valve prolapse may be detected as a heart murmur but there are usually no symptoms.

Premutation—A change in a gene that precedes a mutation; this change does not alter the function of the gene.

X chromosome—One of the two sex chromosomes (the other is Y) containing genetic material that, among other things, determine a person's gender.

Treatment

Presently there is no cure for fragile X syndrome. Management includes such approaches as **speech therapy**, **occupational therapy**, and **physical therapy**. The expertise of psychologists, special education

WWW.BOOKBAZ.IR

teachers, and genetic counselors may also be beneficial. Drugs may be used to treat hyperactivity, seizures, and other problems. Establishing a regular routine, avoiding over-stimulation, and using calming techniques may also help in the management of behavioral problems. Children with a troubled heart valve may need to see a heart specialist and take medications before surgery or dental procedures. Children with frequent ear and sinus infections may need to take medications or have special tubes placed in their ears to drain excess fluid. Mainstreaming of children with fragile X syndrome into regular classrooms is encouraged because they do well imitating behavior. Peer tutoring and positive reinforcement are also encouraged.

Prognosis

Early diagnosis and intensive intervention offer the best prognosis for individuals with fragile X syndrome. Adults with fragile X syndrome may benefit from vocational training and may need to live in a supervised setting. Life span is typically normal.

A 2004 study found that men who are carriers of the fragile X gene but have not have the mutation severe enough to have fragile X syndrome may begin to show signs of tremor disorder, gait instability and memory impairment as they age. The higher prevalence of these symptoms among grandfathers of children with fragile x syndrome was noted so a study was done to investigate their symptoms compared to men of the same age without the mutation. About 17% of the grandfathers in their 50s had the condition, 37% of those in their 60s, 47% of men in their 70s and 75% of men in their 80s. Often, these men have been diagnosed with other diseases such as Parkinson's or Alzheimer's rather than with fragile X-associated tremor/ataxia syndrome, the name which has been given to these late symptoms from the fragile x mutation.

Friedreich's ataxia

Definition

Friedreich's ataxia (FA) is an inherited, progressive nervous system disorder causing loss of balance and coordination.

Description

Ataxia is a condition marked by impaired coordination. Friedreich's ataxia is the most common inherited ataxia, affecting between 3,000–5,000 people in the United States. FA is an autosomal recessive disease, which means that two defective gene copies must be inherited to develop symptoms, one from each parent. A person with only one defective gene copy will not show signs of FA, but may pass along the gene to offspring. Couples with one child affected by FA have a 25% chance in each **pregnancy** of conceiving another affected child.

Causes and symptoms

Causes

The gene for FA codes for a protein called frataxin. Normal frataxin is found in the cellular energy structures known as mitochondria, where it is thought to be involved in regulating the transport of iron. In FA, the frataxin gene on chromosome 9 is expanded with nonsense information known as a "triple repeat." This extra DNA interferes with normal production of frataxin, thereby impairing iron transport. Normally, there are 10-21 repeats of the frataxin gene. In FA, this sequence may be repeated between 200-900 times. The types of symptoms and severity of FA seems to be

associated with the number of repetitions. Patients with more copies have more severe symptomatology. Researchers are still wrestling with how frataxin and the repeats on chromosome 9 are involved in causing FA. One theory suggests that FA develops in part because defects in iron transport prevent efficient use of cellular energy supplies.

The nerve cells most affected by FA are those in the spinal cord involved in relaying information between muscles and the brain. Tight control of movement requires complex feedback between the muscles promoting a movement, those restraining it, and the brain. Without this control, movements become uncoordinated, jerky, and inappropriate to the desired action.

Symptoms

Symptoms of FA usually first appear between the ages of 8 and 15, although onset as early as 18 months or as late as age 25 is possible. The first symptom is usually gait incoordination. A child with FA may graze doorways when passing through, for instance, or trip over low obstacles. Unsteadiness when standing still and deterioration of position sense is common. Foot deformities and walking up off the heels often results from uneven muscle weakness in the legs. **Muscle spasms and cramps** may occur, especially at night.

Ataxia in the arms follows, usually within several years, leading to decreased hand-eye coordination. Arm weakness does not usually occur until much later. Speech and swallowing difficulties are common. **Diabetes mellitus** may also occur. **Nystagmus**, or eye tremor, is common, along with some loss of visual acuity. **Hearing loss** may also occur. A side-to-side curvature of the spine (**scoliosis**) occurs in many cases, and may become severe.

Heartbeat abnormalities occur in about two thirds of FA patients, leading to **shortness of breath** after exertion, swelling in the lower limbs, and frequent complaints of cold feet.

Diagnosis

Diagnosis of FA involves a careful medical history and thorough **neurological exam**. Lab tests include **electromyography**, an electrical test of muscle, and a nerve conduction velocity test. An electrocardiogram may be performed to diagnose heart arrhythmia.

Direct DNA testing is available, allowing FA to be more easily distinguished from other types of ataxia. The same test may be used to determine the presence of the genetic defect in unaffected individuals, such as siblings.

KEY TERMS

Ataxia—A condition marked by impaired coordination.

Scoliosis—An abnormal, side-to-side curvature of the spine.

Treatment

There is no cure for FA, nor any treatment that can slow its progress. Amantadine may provide some limited improvement in ataxic symptoms, but is not recommended in patients with cardiac abnormalities. Physical and **occupational therapy** are used to maintain range of motion in weakened muscles, and to design adaptive techniques and devices to compensate for loss of coordination and strength. Some patients find that using weights on the arms can help dampen the worst of the uncoordinated arm movements.

Heart **arrhythmias** and diabetes are treated with drugs specific to those conditions.

Prognosis

The rate of progression of FA is highly variable. Most patients lose the ability to walk within 15 years of symptom onset, and 95% require a wheelchair for mobility by age 45. Reduction in lifespan from FA complications is also quite variable. Average age at death is in the mid-thirties, but may be as late as the mid-sixties. The particular length of the triple repeat has not been correlated strongly enough with disease progression to allow prediction of the course of the disease on this basis.

Prevention

There is no way to prevent development of FA in a person carrying two defective gene copies.

Frostbite and frostnip

Definition

Frostbite is the term for damage to the skin and other tissues caused by freezing. Frostnip is a milder form of cold injury; it is sometimes described as the first stage of frostbite.

Demographics

Frostbite is most likely to occur among military personnel, people who work outdoors in cold weather, mountain climbers, skiers and other winter sports participants, homeless people, travelers stranded outside in cold weather, and people who live close to the polar regions. In a few cases frostbite is caused by industrial accidents, when workers who must handle liquid nitrogen or other liquefied gases fail to protect their hands or use proper safety equipment. It is estimated that frostbite in North America and northern Europe causes 2.5 hospital admissions per 100,000 people annually. The true rate is unknown because there is no standardized reporting system for this disorder.

Most frostbite victims are male, but this ratio is thought to reflect occupational choices and interest in high-risk outdoor sports rather than a genetic factor.

According to U.S. military statistics, African American male soldiers are 4 times as likely and African American female soldiers 2.2 times as likely to suffer frostbite as their Caucasian or Native American counterparts. Pacific Islanders and other ethnic and racial groups from warmer climates are also thought to be more likely to suffer frostbite. British Army findings are similar. In addition to race, certain diseases, including diabetes, thyroid disorders, arthritis, and some infections increase a person's risk of developing frostbite during exposure to cold.

Most frostbite victims are middle-aged adults between the ages of 35 and 50; one study found the average age of patients treated for frostbite is 41.

Description

Frostbite is most likely to affect the face, hands, and feet; however, the shins, knees, and the outer portions of the eyes may also be affected. Freezing of exposed tissues results in the formation of ice crystals inside the cell wall. There is a variation of frostbite known as mountain frostbite, which affects mountain climbers and others exposed to extremely cold temperatures at high altitude. It combines tissue freezing with oxygen deprivation and general body **dehydration**.

A human hand with frostbite. *(SIU/Photo Researchers, Inc.)*

Risk factors

Risk factors for frostbite and frostnip include:

- military service or employment that requires being outdoors for long periods of time in cold weather or cold climates
- participation in mountain climbing, alpine skiing, or other winter sports
- homelessness
- alcohol or substance abuse
- mental illness
- previous exposure to frostbite or cold injury
- (Nicotine causes blood vessels to constrict, thus lowering the body's ability to circulate blood to the hands, feet, and face.)
- malnutrition
- underlying infection
- medical conditions that affect a person's ability to feel or respond to cold, including dehydration, exhaustion, diabetes, or circulatory disorders

Causes and symptoms

Causes

Frostbite is caused by exposure of skin and underlying tissues to extreme cold, usually environmental. When the skin is exposed to temperatures at or below 32°F (0°C), the blood vessels in the skin start to constrict. This closing down of the blood flow in the extremities is the body's protective strategy for preserving normal body temperature in the body core (the heart and other internal organs).

Skin exposed to temperatures a little below the freezing mark can take hours to freeze, but very cold skin can freeze in minutes or seconds. Air temperature, wind speed, and moisture all affect how cold the skin

becomes. A strong wind can lower skin temperature considerably by dispersing the thin protective layer of warm air that surrounds our bodies. Wet clothing readily draws heat away from the skin because water is a potent conductor of heat. The evaporation of moisture on the skin also produces cooling. For these reasons, wet skin or clothing on a windy day can lead to frostbite even if the air temperature is above the freezing mark.

Three nearly simultaneous physiological processes underlie frostbite injury: tissue freezing, tissue hypoxia, and the release of inflammatory mediators. Tissue freezing causes ice crystal formation and other changes that damage and eventually kill cells. Much of this harm occurs because the ice produces pressure changes that cause water (crucial for cell survival) to flow out of the cells. Tissue hypoxia (oxygen deficiency) occurs when the blood vessels in the hands, feet, and other extremities narrow in response to cold. Among its many tasks, blood transfers body heat to the skin, which then dissipates the heat into the environment. Blood vessel narrowing is the body's way of protecting vital internal organs at the expense of the extremities by reducing heat flow away from the core. However, blood also carries life-sustaining oxygen to the skin and other tissues, and narrowed vessels result in oxygen **starvation**. Narrowing also causes acidosis (an increase in tissue acidity) and increases blood viscosity (thickness). Ultimately, blood stops flowing through the capillaries (the tiny blood vessels that connect the arteries and veins) and **blood clots** form in the arterioles and venules (the smallest arteries and veins). Damage also occurs to the endothelial cells that line the blood vessels. Hypoxia, blood clots, and endothelial damage lead, in turn, to the release of inflammatory mediators (substances that act as links in the inflammatory process), which promote further endothelial damage, hypoxia, and cell destruction.

Symptoms

The early stage of frostbite is sometimes called frostnip. Short-term symptoms include loss of feeling or aching **pain** in the affected part, followed by redness of the skin and tissue swelling. Unfortunately, a victim is often unaware of frostbite until someone else points it out because the frozen tissues are numb. Long-term symptoms include intense pain in the affected part, tingling sensations, cracks in the skin, dry skin, loss of fingernails, joint stiffness, loss of bone or muscle tissue, and increased sensitivity to cold. If left untreated, frostbitten skin gradually darkens and blisters after a few hours. Skin destroyed by frostbite is completely black, looks burnt, and may hang loosely from the underlying tissues.

Diagnosis

Diagnosis of frostbite is usually made in the field on the basis of the appearance of the frostbitten parts of the body. Some doctors use a four-degree classification of injuries:

- First-degree: The epidermis (outermost layer of the skin) is reddened, swollen, and may look waxy. There is also a loss of sensation in the affected skin.
- Second-degree: The skin is reddened, swollen, and has formed blisters filled with a clear or milky fluid.
- Third-degree: The blisters are filled with blood and the skin begins to turn black.
- Fourth-degree: The epidermis, dermis, and underlying muscles, tendons, and bones are damaged.

Examination

Examination of the patient usually has to be done at the scene rather than in a doctor's office, although it can also be conducted in an ambulance, helicopter, or other emergency medical transport. The doctor will examine the condition of the affected parts, including skin color, the presence of blisters, and other features. If the patient has also been injured in an accident, the doctor will also evaluate the patient for sprains, broken bones, and internal injuries.

Tests

A technique that can be used to diagnose the extent of soft-tissue injury after frostbite is technetium scintigraphy. This is a technique in which radioactive technetium is administered intravenously. The radioactive element is taken up differently by healthy and damaged tissue, and the pattern of "hot spots" and "cold spots" as traced by a scanner allows the doctor to tell whether and where deep tissues have been damaged by frostbite. Scintigraphy can also be used to monitor the recovery of the injured tissues following emergency treatment.

X rays and other imaging studies will not help in diagnosing frostbite but may be used to evaluate the injured person for broken or fractured bones.

Treatment

FROSTBITE. Emergency medical help should always be summoned whenever frostbite is suspected. While waiting for help to arrive, one should, if possible, remove wet or tight clothing and put on dry, loose clothing or wraps. A splint and padding are used to protect the injured area. The patient should not be allowed to walk on frostbitten toes or feet, as the weight

WWW.BOOKBAZ.IR

KEY TERMS

Amputation—Surgical removal of a limb.

Debridement—The medical term for the surgical removal of dead or damaged soft tissue.

Dermis—The layer of skin just below the epidermis.

Epidermis—The outermost layer of the skin.

Gangrene—Decay and death of soft tissue due to loss of blood supply.

Hypoxia—The medical term for deprivation of an adequate oxygen supply, either to specific tissues or to the entire organism.

of the body will cause further damage to tissue—unless walking is the only way the patient can get to shelter.

Rubbing the area with snow or anything else is dangerous. The key to prehospital treatment is to avoid partial thawing and refreezing, which releases more inflammatory mediators and makes the injury substantially worse. For this reason, the affected part must be kept away from such heat sources as campfires and car heaters. In addition, the injured person should not be given alcohol or tranquilizers, as these will increase loss of body heat. Experts advise rewarming in the field only when emergency help will take more than two hours to arrive and refreezing can be prevented.

Because the outcome of a frostbite injury cannot be predicted at first, all hospital treatment follows the same route. Treatment begins by rewarming the affected part for 15–30 minutes in water at a temperature of 104–108 °F (40–42.2 °C). This rapid rewarming halts ice crystal formation and dilates narrowed blood vessels. Aloe vera (which acts against inflammatory mediators) is applied to the affected part, which is then splinted, elevated, and wrapped in a dressing. Depending on the extent of injury, blisters may be debrided (cleaned by removing foreign material) or simply covered with aloe vera. Except when injury is minimal, treatment generally requires a hospital stay of several days, during which **hydrotherapy** and **physical therapy** are used to restore the affected part to health. Experts recommend a cautious approach to tissue removal, and advise that 22–45 days must pass before a decision on **amputation** can safely be made.

If frostbitten skin is not treated and its blood vessels are affected, **gangrene** may set in. Gangrene is the death of soft tissue due to loss of blood supply. It may be treated by surgical removal of the affected tissue if caught early; otherwise, the surgeon may have to amputate the affected digit or limb to prevent bacterial infections from spreading from the dead tissue to the rest of the body.

FROSTNIP. Frostnipped fingers are helped by blowing warm air on them or holding them under one's armpits. Other frostnipped areas can be covered with warm hands. The injured areas should never be rubbed.

Drugs

The goals of medical therapy for frostbite are pain control and prevention of such complications as further tissue damage or infection. Patients being treated in the hospital for severe frostbite may be given morphine for **pain management** as **narcotics** are needed in most cases to reduce the excruciating pain that occurs as sensation returns during rewarming. A **tetanus** shot and penicillin G are used to prevent infection, and the patient is given ibuprofen or another NSAID to combat inflammation.

Alternatives

Alternative practitioners suggest several kinds of treatment to speed recovery from frostbite after leaving the hospital. Bathing the affected part in warm water or using contrast hydrotherapy can help enhance circulation. Contrast hydrotherapy involves a series of hot and cold water applications. A hot compress (as hot as the patient can stand) is applied to the affected area for three minutes followed by an ice cold compress for 30 seconds. These applications are repeated three times each, ending with the cold compress. Nutritional therapy to promote tissue growth in damaged areas may also be helpful.

Homeopathic and botanical therapies may also assist recovery from frostbite. Homeopathic *Hypericum* (*Hypericum perforatum*) is recommended when nerve ending are affected (especially in the fingers and toes) and *Arnica* (*Arnica montana*) is prescribed for **shock**. Cayenne pepper (*Capsicum frutescens*) can enhance circulation and relieve pain. Drinking hot ginger (*Zingiber officinale*) tea also aids circulation. Other possible approaches include **acupuncture** to avoid permanent nerve damage and **oxygen therapy**.

Prognosis

Patients with early recovery of sensation in the affected part, blisters filled with clear fluid, and healthy-appearing skin color have a better prognosis for full recovery than those whose skin has turned bluish, has blood-filled blisters, and looks frozen.

People who have recovered from frostbite have an increased risk of another episode during future exposures to cold. They should take extra precautions to dress properly for extreme cold or avoid it altogether. They may also notice that the frostbitten parts of their body are more sensitive to ordinary cold weather, and ache or tingle whenever they are outdoors.

The extreme throbbing pain that many frostbite sufferers endure for days or weeks after rewarming is not the only prolonged symptom of frostbite. Other possible consequences of frostbite include skin—color changes, nail deformation or loss, joint stiffness and pain, **hyperhidrosis** (excessive sweating), and heightened sensitivity to cold. For everyone, a degree of sensory loss lasting at least four years—and sometimes a lifetime—is inevitable. About 65% of people with severe frostbite will eventually develop arthritis in the affected hand, foot, or leg.

Prevention

With the appropriate knowledge and precautions, frostbite can be prevented even in the coldest and most challenging environments. Appropriate clothing and footwear are essential. To prevent heat loss and keep the blood circulating properly, clothing should be worn loosely and in layers. Covering the hands, feet, and head is also crucial for preventing heat loss; mittens are better than gloves for keeping hands warm. Outerwear should be wind- and water-resistant; and wet clothing and footwear must be replaced as quickly as possible. People should also be aware of the early warning signs of frostbite, which include redness of the skin, prickling sensations, and numbness.

Alcohol and drugs should be avoided because of their harmful effects on judgment and reasoning. Experts also warn against alcohol use and **smoking** in the cold because of the circulatory changes they produce. Paying close attention to the weather report before venturing outdoors and avoiding such unnecessary risks as driving in isolated areas during a blizzard are also important precautionary measures. In addition, when traveling in cold weather, people should carry emergency supplies and warm clothing in case they become stranded. Last, people who are hiking or skiing in cold temperatures should use a buddy system in case one person is injured and must be evacuated quickly.

Fugu poisoning

Definition

Fugu **poisoning** occurs when a person eats the flesh of a fugu, also known as a puffer fish, which contains lethal toxins.

Description

Fugu, also known as puffer fish, blowfish, or globefish, has long been a food delicacy in Japan, but has only been introduced in the United States in the last 30-40 years. The fugu and related species may contain a tetrodotoxin, an extremely potent neurotoxin and one of the most toxic substances known, which produces critical illness and often death. Between January 1 and April 1, 2002, at least 10 cases of fugu poisoning were reported in the United States, according to the Centers for Disease Control and Prevention (CDC) in Atlanta, Georgia. All persons recovered from the poisonings. All of the fish came from the Atlantic Ocean off the coast of Titusville, Florida. Fugu caught in southern U.S. waters, such as the Gulf of Mexico, may also be toxic. Tetrodotoxin has been detected in pufferfish throughout the Pacific Ocean and the Baja California coastal region. Cases of fugu poisoning are sporadically diagnosed, but many more are not recognized or reported. The earliest cases reported to the CDC involved poisonings in Florida during the mid-1970s. Since 1950, only three known fatalities have occurred in the United States, all in Florida.

The dangers of puffer fish consumption have long been recognized. Artifacts recovered from an Egyptian tomb indicate that puffer fish poisoning has been known since approximately 2400–2700 B.C. In journals covering expeditions from 1772-1775, Pacific explorer Captain James Cook provided a vivid description of what some believe to be puffer fish poisoning. Fugu are found in waters throughout the world. Scientists have found that toxic fugu have unique exocrine glands for the secretion of tetrodotoxin. The fish appear to actively produce the toxin, rather than passively acquire it from the environment. For these fish, tetrodotoxin may serve as a natural defense mechanism to repel predators. The flesh of the fugu is generally eaten raw in paper-thin slices, known as sashimi. Part of the reported delight in eating fugu is the tingling oral sensation induced by minute amounts of tetrodotoxin in the flesh. For this reason, eating fugu is considered an "experience," rather than just a meal in Japan. The experience is expensive, however, since a plate of this delicacy can cost as much as $500.

Causes and symptoms

The most common symptoms of fugu poisioning are tingling and burning of the mouth and tongue, numbness, drowsiness, and incoherent speech. These symptoms usually occur 30 minutes to two hours after ingestion of the fish, depending on the amount of toxin ingested. In severe cases, ataxia (the inability to coordinate the movements of muscles), muscle weakness, **hypotension** (low blood pressure) and cardiac **arrhythmias** (irregular heartbeat) may develop, followed by muscle twitching and respiratory **paralysis**, and death can occur. In several cases, people died within 17 minutes after eating pufferfish.

Diagnosis

The initial diagnosis is usually made by observation of early symptoms, including an abnormal or unexplained tingling, pricking, or burning sensation on the skin around the mouth and throat. Definitive diagnosis can only be made in a medical laboratory by examination of the ingested fish and identification of the specific toxins. Ill persons should be advised to proceed to a hospital emergency department and contact their local poison control center.

Treatment

There is no antidote for fugu poisoning, therefore treatment is limited to supportive measures and the removal of the unabsorbed toxin. If spontaneous

KEY TERMS

Ataxia—A lack of muscle control.

Arrhythmia—An irregularity in the normal rhythm or force of the heartbeat.

Atropine—A poisonous alkaloid obtained from belladonna or related plants, used medically to dilate the pupils of the eyes and to stop spasms.

Endoscopy—The use of a medical instrument consisting of a long tube inserted into the body, usually through a small incision, for diagnostic examination and surgical procedures.

Exocrine—Relating to external secretion glands, such as sweat glands or salivary glands that release a secretion through a duct to the surface of an organ.

Hypotension—Low blood pressure.

Lavage—The washing out of a hollow body organ, for example, the stomach, using a flow of water.

Neurotoxin—A substance that damages, destroys, or impairs the functioning of nerve tissue.

vomiting does not occur, it should be induced. Gastric lavage (stomach washing) with an alkaline solution has been suggested, as well as **endoscopy** to remove the poison from the proximal small bowel. Following lavage, **activated charcoal** is reported to effectively bind the toxin. Other steps include administration of oxygen, assisted breathing, intravenous atropine for bradycardia (slow heartbeat) and intravenous fluids, along with dopamine, to manage hypotension. Since tetrodotoxins and opiates are similar, use of an opiate antagonist may be useful, according to the American Academy of Family Physicians.

Prognosis

The mortality rate may be as high as 60%. Epidemiologic evidence suggests that recovery can be expected if an affected person survives beyond 24 hours. After 24 hours, a person with fugu poisoning usually makes a full recovery.

Prevention

The only prevention is not to eat any of the species of fugu that contain toxins.

Functional endoscopic sinus surgery

Definition

Functional endoscopic sinus surgery (FESS) is a minimally invasive surgical procedure that opens up sinus air cells and sinus ostia (openings) with an endoscope.

The use of FESS as a sinus surgical method has now become widely accepted. The term "functional" is meant to distinguish this type of endoscopic surgery from nonendoscopic, more conventional sinus surgery procedures.

Purpose

The purpose of FESS is to restore normal drainage of the sinuses. This function requires ventilation through the ostia (mouth-like opening) and is facilitated by a mucociliary transport process that maintains a constant flow of mucus out of the sinuses. All sinuses need ventilation to prevent infection and inflammation, a condition known as **sinusitis**. In healthy individuals, sinus ventilation occurs through the ostia into the nose. The sinuses open into the

WWW.BOOKBAZ.IR

middle meatus (curved passage in each nasal cavity) under the middle turbinate (thin, bony process that is the lower portion of the ethmoid bone in each nasal cavity), which together are known as the osteomeatal complex, the key area of the nose. The hair-like cilia direct the flow of mucus toward the ostia.

Sinusitis develops when there is a problem in the area where the maxillary and frontal sinuses meet near the nose or, occasionally, a dental infection. When sinusitis occurs, the cilia work less efficiently, preventing the flow of mucus. The mucous membranes of the sinuses become engorged, resulting in ostia closure. Poor ventilation and accumulation of mucus then produce the conditions required for bacterial infection.

Demographics

Sinusitis is a very common condition, affecting 31 million Americans each year. Thirty percent of the U.S. population has sinusitis at some point in their lives. The average adult has three to four upper respiratory infections a year; 1% of these infections are complicated by sinusitis, accounting for 16 million visits to the doctor each year. Approximately 200,000 surgical procedures are performed annually for the treatment of sinus problems.

Description

This procedure is usually performed on an outpatient basis by an ear, nose, and throat (ENT) specialist, such as an otolaryngologist or an ophthalmic surgeon. ENT physicians are graduates of a school of medicine and typically undergo an otolaryngology residency with further specialization in sinus disease and endoscopic sinus surgery.

After inducing adequate vasoconstriction with cocaine or ephedrine, the surgeon locates the middle turbinate, the most important landmark for the FESS procedure. On the side of the nose at the level of the middle turbinate lies the uncinate process, which the surgeon removes. The surgeon opens the back ethmoid air cells, to allow better ventilation, but leaves the bone covered with the mucous membrane. Following this step, the ostium located near the jaw is checked for obstruction and, if necessary, opened with a middle meatal antrostomy. This surgical procedure often greatly improves the function of the osteomeatal complex and provides better ventilation of the sinuses. The surgical procedure is often performed on an outpatient basis.

FESS offers several advantages:

- It is a minimally invasive procedure.
- It does not disturb healthy tissue.
- It is performed in less time with better results.
- It minimizes bleeding and scarring.

Preparation

As with many diseases, the history of a patient with sinusitis represents a key part of the preoperative evaluation. Before considering FESS, the ear, nose and throat (ENT) specialist will proceed with a thorough diagnostic examination. The development of such diagnostic tools as **endoscopy** and computed tomography (CT) scanning has greatly improved the treatment of sinus disease. The fiberoptic endoscope is used to examine the nose and all its recesses thoroughly. The specific features that the physician must examine and evaluate are the middle turbinate and the middle meatus, any anatomic obstruction, and the presence of pus and **nasal polyps**.

CT scanning can also be used to identify the diseased areas, a process that is required for planning the surgery. It shows the extent of the affected sinuses, as well as any abnormalities that may make a patient more susceptible to sinusitis.

FESS is usually performed under local **anesthesia** with intravenous **sedation** on an outpatient basis with patients going home one to two hours after surgery. It usually does not cause facial swelling or bruising and does not generally require **nasal packing**.

Aftercare

FESS usually does not cause severe postoperative sinus **pain**. After the procedure, it is important to keep the nose as free from crust build-up as possible. To achieve this, the surgeon may perform a lengthy cleaning two to three times per week, or the patient may perform a simple nasal douching several times a day. Normal function usually reappears after one or two months. In patients with severe sinusitis or polyps, a short course of systemic **steroids** combined with **antibiotics** may quicken recovery.

Results

The FESS procedure is considered successful if the patient's sinusitis is resolved. Nasal obstruction and facial pain are usually relieved. The outcome has been compared with that of the Caldwell-Luc procedure and, although both methods are considered effective, there is a strong patient preference for FESS. The extent of the disease before surgery dictates the outcome, with the best results obtained in patients with limited nasal sinusitis. The disease may not be cured

KEY TERMS

Antrostomy—The operation of opening an antrum (cavity) for drainage.

Caldwell-Luc procedure—A surgical procedure in which the surgeon enters the maxillary sinus by making an opening under the upper lip above the teeth.

Cilia—Short hairlike processes that are capable of a lashing movement.

Endoscope—An instrument for visualizing the interior of a hollow organ.

Ethmoid sinuses—Paired labyrinth of air cells between the nose and eyes.

Maxillary sinuses—Sinuses located in the cheek under the eye next to the ethmoid sinus.

Meatus—A general term for an opening or passageway in the body.

Middle meatus—A curved passage in each nasal cavity located below the middle nasal concha and extending along the entire superior border of the inferior nasal concha.

Middle turbinate—The lower of two thin bony processes on the ethmoid bone on the lateral wall of each nasal fossa that separates the superior and middle meatus of the nose.

Mucociliary—Involving cilia of the mucous membranes of the respiratory system.

Mucous membrane—A membrane rich in mucous glands that lines body passages and cavities communicating directly or indirectly with the exterior of the body (as for example, the alimentary, respiratory, and genitourinary tracts). Mucous membranes functions in protection, support, nutrient absorption, and secretion of mucus, enzymes, and salts.

Mucus—A viscous, slippery secretion that is produced by the mucous membranes it moistens and protects.

Nasal concha—Any of three thin bony plates on the lateral wall of the nasal fossa on each side with or without their covering of mucous membrane.

Ostia—A mouth-like opening in a bodily part.

Polyp—A projecting mass of swollen and hypertrophied or tumorous tissue.

Sinus—A cavity in a bone of the skull that usually communicates with the nostrils and contains air.

Sinusitis—Inflammation of a sinus.

Turbinate—Relating to a nasal concha.

Uncinate process—A downwardly and backwardly directed process of each lateral mass of the ethmoid bone that joins with the inferior nasal conchae.

Vasoconstriction—Narrowing of blood vessels, especially as a result of vasomotor action.

and may recur at a later time. Subsequent sinus procedures may be necessary.

Risks

The most serious risk associated with FESS is blindness resulting from damage to the optic nerve. However, the chances of this complication occurring are extremely low. Cerebrospinal fluid leak represents the most common major complication of FESS, but it occurs in only about 0.2% of cases in the United States. The leak is usually recognized at the time of surgery and can easily be repaired. Other less serious and rare complications include orbital hematoma and nasolacrimal duct stenosis (narrowing). All of these complications are also associated with conventional sinus surgery and not only with FESS.

Morbidity and mortality rates

According to the American Academy of Family Physicians (AAFP), FESS usually has a good outcome, with most studies reporting an 80–90% rate of success. Good results have also been obtained in patients who have had previous sinus surgery.

Alternatives

Image-guided endoscopic surgery uses image guidance techniques that feature a three-dimensional mapping system combining CT scanning and real-time data acquisition concerning the location of the surgical instruments during the procedure. It allows surgeons to navigate more precisely in the affected area. The surgeon can monitor the exact location of such vital organs as the brain and eyes as well as positively identifying the affected areas.

Another option, the Caldwell-Luc procedure, improves drainage in the maxillary sinus region located below the eye. The surgeon reaches the region through the upper jaw above one of the second molars. He or she creates a passage to connect the maxillary sinus to the nose in order to improve drainage.

Fungal infections

Definition

Fungal infections are a group of diseases caused by fungi, which are members of a large group of eukaryotic organisms that do not contain chlorophyll, but have cell walls and filamentous structures, and produce spores. Fungi include microorganisms that cause disease as well as visible yeasts, molds, and mushrooms. There may be as many as 1–5 million species of fungi in the environment, but only about 5% of them have been formally classified. About 320 species are known to cause disease in humans and other animals. Diseases caused by fungi are called mycoses (singular, mycosis), and the study of fungal infections is called medical mycology. The English word *fungus* is the Latin word for mushroom.

Description

Fungal infections are grouped into categories according to the level of body tissues that are initially infected:

- Superficial mycoses: These are fungal infections that affect only the outermost layers of the skin or hair; do not invade deeper layers of tissue; and do not elicit an immune response from the host. Most superficial mycoses are caused by yeasts. They include such common problems as dandruff; it is possible for a person to have a superficial mycosis and be unaware of it. Another superficial mycosis is tinea versicolor, a yeast infection of the upper layer of the skin that causes discoloration or mild flaking of the skin but is otherwise harmless. Tinea versicolor is most common in people who live in the tropics or subtropics.
- Cutaneous mycoses: These are invasive fungal infections of the lower layers of the skin, hair, or nails; they differ from the superficial mycoses in that they trigger immune responses in the host. Most are caused by dermatophytes, most commonly *Microsporum*, *Trichophyton*, and *Epidermophyton* species. They include such infections as ringworm, tinea cruris (jock itch), tinea pedis (athlete's foot), and tinea barbae (fungal infection of the bearded areas of the face and neck in adult males). The cutaneous mycoses also include infections caused by *Candida albicans*, such as thrush (oral candidiasis) and vaginal yeast infections.
- Subcutaneous mycoses: These are infections of the layers of tissue beneath the skin, such as muscles and fascia. They usually result from piercing or penetrating injuries that allow the fungi to enter

Typical skin lesion caused by ringworm, a fungal infection. *(Mediscan/Medical-on-Line/Alamy.)*

deep tissue layers. Subcutaneous mycoses include sporotrichosis, mycotic mycetoma, and chromoblastomycosis. These mycoses are fortunately rare but are difficult to treat and may require surgical intervention.

- Systemic mycoses caused by primary pathogens: These infections usually begin in the lungs and spread to other organs and organ systems. They are also rare. They include such diseases as histoplasmosis, coccidioidomycosis (valley fever), blastomycosis, and sporotrichosis.
- Systemic mycoses caused by opportunistic pathogens: These infections occur in patients with weakened immune systems who would not otherwise be susceptible to these fungi. Examples include invasive candidiasis, cryptococcosis, mucormycosis, and aspergillosis. Although opportunistic fungal infections are almost always limited to persons with weakened immune systems, they have become more common in recent years because of the expanded use of antibiotics and corticosteroids, more aggressive chemotherapy for cancer, and increased numbers of organ or stem cell transplants. Some of these infections are nosocomial in origin, which means that they are contracted in hospitals.

Risk factors

Superficial and cutaneous mycoses are widespread in the general population because the organisms that cause them are ubiquitous in the environment. Risk factors for such infections as athlete's foot, **ringworm**, **jock itch**, and others caused by dermatophytes are largely environmental, as these fungi thrive in warm, moist environments and can infect anyone, including healthy people as well as those with weakened immune systems. Specific risk factors for these infections include:

- living in a hot, humid climate
- sharing communal baths or showers
- sharing towels or bedding
- participating in wrestling or other contact sports
- living in overcrowded housing, dormitories, or military barracks
- sharing combs or brushes
- having close contact with domestic pets or other animals

Risk factors for systemic and opportunistic fungal infections include:

- having HIV infection or AIDS
- being hospitalized; this is a risk factor for invasive candidiasis
- taking immunosuppressant drugs
- having cancer
- living in certain areas of the United States, particularly the Mississippi Valley
- employment as a gardener, woodcutter, construction worker, forester, field biologist, or other occupation that involves excavation or disruption of soil and organic matter
- having received a stem cell transplant
- having received a solid organ transplant
- having recently been treated with antibiotics

Demographics

Demographics of fungal infections differ according to the severity and invasiveness of the infection. Superficial and cutaneous fungal infections are very common in the general population in all countries because these fungi are widely distributed in the general environment. One journal estimated in 2014 that these skin infections are the fourth most common cause of disease worldwide, affecting as many as 984 million people. About 20% of the general population in the developed countries is thought to have cutaneous fungal infections like ringworm, fungal infections of the nails (**onychomycosis**), or athlete's foot at any given time; and about 75% of women will have vaginal **candidiasis** at least once in their lifetime.

Subcutaneous and systemic fungal infections are much less common than those that affect the skin, hair, and nails. **Histoplasmosis**, a fungal infection spread by inhaling fungal spores released into the air from the droppings of infected birds and bats, affects

WWW.BOOKBAZ.IR

about 3 to 5 people per 100,000 in the American adult population. **Mucormycosis**, a rare infection caused by fungi that live in decaying leaves, rotten wood, and similar organic matter, affects about 1.7 persons per million in the United States. **Coccidioidomycosis**, also known as valley **fever**, is most common in the Mississippi Valley and the American Southwest, where its incidence is about 50 per 100,000 persons. **Blastomycosis**, a lung infection that results from inhaling fungal spores produced by rotting leaves, wood, and similar organic matter, affects about 2 persons per 100,000, and is more common in the Midwest than in other areas of the United States. **Aspergillosis**, a lung infection, is an example of an opportunistic fungal infection; it is most common in persons with **AIDS**, those who have received organ transplants, and those who have received stem cell transplants.

Most fungal infections affect either isolated individuals or small groups of people who share personal items or use sports facilities or daycare centers. Larger outbreaks are rare, but have been reported in prisons and ICUs, or in the aftermath of a natural disaster such as the tornado that struck Joplin, Missouri, in 2011. A more recent but worrisome cause of outbreaks of fungal disease is contaminated medications, particularly steroid injections.

Causes and symptoms

Fungal infections in humans are caused by either contact with an infected person, animal, or surface, in the case of the superficial and cutaneous mycoses; or by inhaling fungal spores released into the atmosphere by fungi in decaying organic matter or in the droppings of infected birds or bats. The subcutaneous mycoses result most commonly from a wound infected by fungal spores.

The symptoms of fungal infections vary according to the level of the tissues affected:

- Superficial mycoses: no or few symptoms; usually limited to mild skin discoloration or flaking.
- Cutaneous mycoses: symptoms may include itching, scaling, cracking, or reddening of the affected skin; white patches on or under the nails; hair loss from the scalp. Symptoms of oral candidiasis include sore and painful mouth, difficulty swallowing, and white patches on the mucous membranes lining the mouth and throat. Vaginal candidiasis is characterized by reddening of the vaginal tissue and a thick whitish discharge.
- Subcutaneous mycoses: Symptoms may include small nodules at the site where the fungus entered the body through a break in the skin, usually on the hand, finger, or arm. The nodule may be reddish or purple and resemble an insect bite. It will grow larger in size and resemble an ulcer, oozing a purulent or watery discharge, and may spread along nearby lymphatic channels. In people with weakened immune systems, the infection can spread to other parts of the body, including the bones, joints, and the central nervous system. If the person has inhaled the spores, he or she may develop a pneumonia-like illness with fever, difficulty breathing, and cough. Anyone who thinks they may have a subcutaneous fungal infection should see a doctor at once.
- Systemic primary mycoses like histoplasmosis are characterized by fever, cough, headache, chills, chest pains, and fatigue. The symptoms appear between 3 and 17 days after the person has inhaled the fungal spores. In people with weakened immune systems, the infection can spread to the brain and spinal cord. In blastomycosis, another primary systemic fungal infection, the patient may develop ulcerated skin lesions if the infection spreads beyond the lungs through the bloodstream. Blastomycosis can also spread to the central nervous system, or into the joints, causing arthritis-like symptoms.
- Systemic opportunistic mycoses are characterized by fever, coughing, wheezing, chest pain, fatigue, and difficulty breathing. These symptoms are not specific to invasive candidiasis, aspergillosis, or mucormycosis, and the doctor will need to conduct laboratory tests to identify the specific fungus that is responsible for the patient's symptoms.

Diagnosis

Diagnosis of superficial fungal infections is done by examining flakes from the affected area of skin under a microscope after a solution of potassium hydroxide (KOH solution) is added. The fungus will have a "spaghetti and meatballs" appearance. The patient's skin may also be examined under a Wood's lamp, a diagnostic device that emits ultraviolet light. Tinea versicolor will fluoresce a pale greenish color under Wood's lamp.

Diagnosis of cutaneous fungal infections is usually done by obtaining scrapings from the affected areas of skin, nail scrapings, or hairs removed from the affected areas. The specimens may be examined under a microscope after adding 10% potassium hydroxide to reveal the characteristic structure of the fungi, or the specimens may be sent to a laboratory for culture, which may take several weeks. Specimens taken from the vagina are usually examined only under the microscope.

Diagnosis of subcutaneous infections is similar to the diagnosis of cutaneous infections. The doctor takes a swab from the affected site or a **skin biopsy** and sends it to a laboratory for analysis.

Diagnosis of primary systemic fungal infections is done by taking skin scrapings, washings from the lungs, samples of blood, urine, bone marrow, or sputum, or tissue biopsies, and sending them to a laboratory for analysis. Specimens must be handled with extreme care as the fungi that cause these systemic infections are a biohazard to laboratory personnel.

Diagnosis of opportunistic systemic infections may involve imaging studies (usually x rays of the lungs) as well as sputum samples and skin biopsies. Blood samples are also taken in patients with compromised immune systems. As the organisms that cause opportunistic infections are not considered highly virulent in people with normal immune systems, laboratory samples are not considered to be biohazards.

Treatment

Superficial infections may not require treatment; or can be treated with over-the-counter creams or shampoos.

Cutaneous fungal infections are treated with antifungal medications. Uncomplicated skin infections may be treated with topical creams or lotions, most often products containing ketoconazole, clotrimazole, miconazole, terbinafine, or naftifine. These are applied twice daily until symptoms improve, usually one or two weeks. Infections of the nails and scalp usually require systemic treatment with oral terbinafine, itraconazole, or fluconazole; the course of oral medication may last from 2 to 6 weeks, depending on the severity of the infection. Nail infections may also be treated with lasers, although this form of therapy is still considered experimental.

Treatment of subcutaneous fungal infections usually involves oral itraconazole for 3 to 6 months; or 12 months if the infection has spread to the joints. Saturated potassium iodide (SSKI) is also sometimes given for this type of fungal infection. Surgical drainage of infected joints and removal of damaged bone may also be necessary.

Treatment of systemic primary fungal infections may not always be needed, as some cases of histoplasmosis resolve without treatment. Prescription antifungal drugs (usually itraconazole) are, however, needed to treat severe disease in the lungs, chronic systemic disease, and infections that have spread from the lungs to other parts of the body (disseminated infection). Blastomycosis is also treated with itraconazole; however, patients with more severe infections may require more aggressive treatment with amphotericin B.

Treatment of opportunistic systemic infections usually involves such antifungal drugs as oral voriconazole, which is the drug of choice as of 2014; although itraconazole, lipid amphotericin formulations, caspofungin, micafungin, and posaconazole can also be used. If the patient is taking immunosuppressive medications, they should be decreased or stopped whenever possible. In extreme cases of invasive aspergillosis, surgery may be required.

Prognosis

The prognosis of fungal infections depends on their location in the body, degree of invasiveness, the specific infectious agent, and the patient's overall health.

- Superficial mycoses: Have an excellent prognosis.
- Cutaneous mycoses: Most infections of the skin, hair, and nails have a very good prognosis and can be cleared up with the use of topical or oral antifungal drugs.
- Subcutaneous mycoses: The prognosis is generally good except for patients with weakened immune systems or those whose subcutaneous infection spreads to other organs. Most infections of this type are non-life-threatening although they may involve a lengthy course of treatment.
- Systemic primary mycoses: About 95% of patients recover without complications or chronic health issues; the remaining 5% develop chronic skin or systemic disorders, or an acute fatal systemic infection.
- Systemic opportunistic mycoses: the prognosis depends on the specific fungus, the speed of identification and treatment; and the reason for the patient's weakened immune system (cancer, HIV infection, stem cell transplant, etc.), but these infections are potentially life-threatening. The mortality rate of opportunistic aspergillosis runs as high as 59%; the mortality rate of invasive mucormycosis, 50%

Prevention

The Centers for Disease Control and Prevention (CDC) recommends the following preventive measures to avoid cutaneous fungal infections:

- Keep the skin dry and clean as much as possible; pay particular attention to the folds of the body (especially the area under the breasts in women and the crotch area in men) and the webs between the toes.

WWW.BOOKBAZ.IR

KEY TERMS

Cutaneous—Referring to a disorder or treatment on or affecting the skin.

Dermatophytes—Fungi that cause infections of the skin, hair, and nails.

Eukaryote—Any organism with cells that contain a nucleus and organelles enclosed within membranes. Fungi are eukaryotes that lack chlorophyll.

Mycology—The branch of biology that deals with the systematic study of fungi.

Mycosis (plural, mycoses)—The medical term for a fungal infection.

Nosocomial—Pertaining to or acquired in a hospital.

Onychomycosis—The medical term for a fungal infection of the nails.

Opportunistic infection—An infection caused by a disease organism that does not cause illness in a healthy person but does cause disease in a person with a weakened immune system.

Tinea—The generic name of a very common fungal infection of the skin, often called simply ringworm. Tinea cruris is the medical term for jock itch; tinea barbae, fungal infection of the beard area in males; and tinea pedis, athlete's foot.

Wood's lamp—A diagnostic instrument that shines ultraviolet light on a patient's skin to help dermatologists diagnose fungal infections of the skin.

- Avoid sharing hats, scarves, combs, brushes, barrettes, and other hair ornaments; the combs and brushes used in barbershops and beauty salons should be disinfected after each use
- Avoid sharing towels, sheets, or sports equipment
- Wash clothes or bedding in hot water after suspected exposure to ringworm or athlete's foot
- Do not go barefoot in locker rooms or at the beach; wear appropriate protective footgear.
- Household pets that show hair loss or other signs of a fungal skin infection should be seen by a veterinarian and given appropriate treatment; they should not be allowed to sleep on human beds, and their own bedding should be washed in hot water.

Preventive recommendations for subcutaneous and systemic fungal infections include:

- Wear gloves when gardening, clearing dead or rotting wood from a property, or when handling diseased animals or their manure.
- Clean scrapes or cuts promptly and thoroughly.
- Avoid areas with high levels of dust like excavations or construction sites; if they cannot be avoided, wear an N95 respirator (a type of face mask).
- Ask the doctor about prophylactic medication to prevent fungal infections caused by breathing fungal spores.
- Ask the doctor whether periodic blood tests to detect invasive opportunistic mycoses as early as possible may be beneficial.
- Hospitals should follow strict infection control procedures to minimize the risk of invasive candidiasis in inpatients, and patients with central venous catheters should ask whether the central line is necessary, and if so, for how long.

Galactorrhea

Definition

Galactorrhea is the secretion of breast milk in men, or in women who are not **breastfeeding** an infant.

Description

Lactation, or the production of breast milk, is a normal condition occurring in women after delivery of a baby. Many women who have had children may even be able to express a small amount of breast milk from the nipple up to two years after **childbirth**. Galactorrhea, or hyperlactation, however, is a rare condition that can occur in both men and women, where a white or grayish fluid is secreted by the nipples of both breasts. While this condition is not serious in itself, galactorrhea can indicate more serious conditions, including hormone imbalances or the presence of tumors.

Causes and symptoms

Causes

Galactorrhea is associated with a number of conditions. The normal production of breast milk is controlled by a hormone called prolactin, which is secreted by the pituitary gland in the brain. Any condition that upsets the balance of hormones in the blood or the production of hormones by the pituitary gland or sexual organs can stimulate the production of prolactin.

Often, a patient with galactorrhea will have a high level of prolactin in the blood. A tumor in the pituitary gland can cause this overproduction of prolactin. At least 30% of women with galactorrhea, menstrual abnormalities, and high prolactin levels have a pituitary gland tumor. Other types of brain tumors, head injuries, or encephalitis (an infection of the brain) can also cause galactorrhea.

Tumors or growths in the ovaries or other reproductive organs in women, or in the testicles or related sexual organs of men, can also stimulate the production of prolactin. Any discharge of fluid from the breast after a woman has passed **menopause** may indicate **breast cancer**. However, most often the discharge associated with breast cancer will be from one breast only. In galactorrhea both breasts are usually involved. The presence of blood in the fluid discharged from the breast could indicate a benign growth in the breast tissue itself. In approximately 10–15% of patients with blood in the fluid, carcinoma of the breast tissue is present.

A number of medications and drugs can also cause galactorrhea as a side-effect. Hormonal therapies (like **oral contraceptives**), drugs for treatment of depression or other psychiatric conditions, tranquilizers, morphine, heroin, and some medications for high blood pressure can cause galactorrhea.

Several normal physiologic situations can cause production of breast milk. Nipple stimulation in men or women during sexual intercourse may induce lactation, for women particularly during or just after **pregnancy**.

Even after extensive testing, no specific cause can be determined for some patients with galactorrhea.

Symptoms

The primary symptom of galactorrhea is the discharge of milky fluid from both breasts. In women, galactorrhea may be associated with **infertility**, menstrual cycle irregularities, hot flushes, or amenorrhea—a condition where menstruation stops completely. Men

WWW.BOOKBAZ.IR

may experience loss of sexual interest and **impotence**. Headaches and visual disturbances have also been associated with some cases of galactorrhea.

Diagnosis

Galactorrhea is generally considered a symptom that may indicate a more serious problem. Collection of a thorough medical history, including pregnancies, surgeries, and consumption of drugs and medications is a first step in diagnosing the cause of galactorrhea. A **physical examination**, along with a breast examination, will usually be conducted. Blood and urine samples may be taken to determine levels of various hormones in the body, including prolactin and compounds related to thyroid function.

A mammogram (an x ray of the breast) or an **ultrasound** scan (using high frequency sound waves) might be used to determine if there are any tumors or cysts present in the breasts themselves. If a tumor of the pituitary gland is suspected, a series of computer assisted x rays called a computed tomography scan (CT scan) may be done. Another procedure that may be useful is a **magnetic resonance imaging** (MRI) scan to locate tumors or abnormalities in tissues.

Treatment

Treatment for galactorrhea will depend on the cause of the condition and the symptoms. The drug bromocriptine is often prescribed first to reduce the secretion of prolactin and to decrease the size of **pituitary tumors**. This drug will control galactorrhea symptoms and in many cases may be the only therapy necessary. Oral estrogen and progestins (hormone pills, like birth control pills) may control symptoms of galactorrhea for some women. Surgery to remove a tumor may be required for patients who have more serious symptoms of **headache** and vision loss, or if the tumor shows signs of enlargement despite drug treatment. **Radiation therapy** has also been used to reduce tumor size when surgery is not possible or not totally successful. A combination of drug, surgery, and radiation treatment can also be used.

Galactorrhea is more of a nuisance than a real threat to health. While it is important to find the cause of the condition, even if a tumor is discovered in the pituitary gland, it may not require treatment. With very small, slow-growing tumors, some physicians may suggest a "wait and see" approach.

Prognosis

Treatment with bromocriptine is usually effective in stopping milk secretion, however, symptoms may recur if drug therapy is discontinued. Surgical removal or radiation treatment may correct the problem permanently if it is related to a tumor. Frequent monitoring of hormone status and tumor size may be recommended.

KEY TERMS

Amenorrhea—Abnormal cessation of menstruation.

Bromocriptine—Also known as Parlodel, the main drug used to treat galactorrhea by reducing levels of the hormone prolactin.

Hyperlactation—Another term for galactorrhea.

Lactation—The production of breast milk.

Prevention

There is no way to prevent galactorrhea. If the condition is caused by the use of a particular drug, a patient may be able to switch to a different drug that does not have the side-effect of galactorrhea.

Galactosemia

Definition

Galactosemia is an inherited disease in which the transformation of galactose to glucose is blocked, allowing galactose to increase to toxic levels in the body. If galactosemia is untreated, high levels of galactose cause **vomiting**, **diarrhea**, lethargy, low blood sugar, brain damage, **jaundice**, liver enlargement, **cataracts**, susceptibility to infection, and death.

Description

Galactosemia is a rare but potentially life-threatening disease that results from the inability to metabolize galactose. Serious consequences from galactosemia can be prevented by screening newborns at birth with a simple blood test.

Galactosemia is an inborn error of metabolism. "Metabolism" refers to all chemical reactions that take place in living organisms. A metabolic pathway is a series of reactions where the product of each step in the series is the starting material for the next step. Enzymes are the chemicals that help the reactions occur. Their ability to function depends on their structure, and their structure is determined by the deoxyribonucleic acid (DNA) sequence of the genes that encode them. Inborn errors of metabolism are caused by mutations in these genes which do not allow the enzymes to function properly.

Sugars are sometimes called "the energy molecules," and galactose and glucose are both sugars. For galactose to be utilized for energy, it must be transformed into something that can enter the metabolic pathway that converts glucose into energy (plus water and carbon dioxide). This is important for infants because they typically get most of their nutrient energy from milk, which contains a high level of galactose. Each molecule of lactose, the major sugar constituent of milk, is made up of a molecule of galactose and a molecule of glucose, and so galactose makes up 20% of the energy source of a typical infant's diet.

Three enzymes are required to convert galactose into glucose-1-phosphate (a phosphorylated glucose that can enter the metabolic pathway that turns glucose into energy). Each of these three enzymes is encoded by a separate gene. If any of these enzymes fail to function, galactose build-up and galactosemia result. Thus, there are three types of galactosemia with a different gene responsible for each.

Every cell in a person's body has two copies of each gene. Each of the forms of galactosemia is inherited as a recessive trait, which means that galactosemia is only present in individuals with two mutated copies of one of the three genes. This also means that carriers, with only one copy of a gene mutation, will not be aware that they are carrying a mutation (unless they have had a genetic test), as it is masked by the normal gene they also carry and they have no symptoms of the disease. For each step in the conversion of galactose to glucose, if only one of the two copies of the gene controlling that step is normal (i.e. for carriers), enough functional enzyme is made so that the pathway is not blocked at that step. If a person has galactosemia, both copies of the gene coding for one of the enzymes required to convert glucose to galactose are defective and the pathway becomes blocked. If two carriers of the same defective gene have children, the chance of any of their children getting galactosemia (the chance of a child getting two copies of the defective gene) is 25% (one in four) for each **pregnancy**.

Classic galactosemia occurs in the United States about one in every 50,000–70,000 live births.

Causes and symptoms

Galactosemia I

Galactosemia I (also called classic galactosemia), the first form to be discovered, is caused by defects in both copies of the gene that codes for an enzyme called galactose-1-phosphate uridyl transferase (GALT). There are 30 known different mutations in this gene that cause GALT to malfunction.

Newborns with galactosemia I appear normal at birth, but begin to develop symptoms after they are given milk for the first time. Symptoms include vomiting, diarrhea, lethargy (sluggishness or **fatigue**), low blood glucose, jaundice (a yellowing of the skin and eyes), enlarged liver, protein and amino acids in the urine, and susceptibility to infection, especially from gram negative bacteria. Cataracts (a grayish white film on the eye lens) can appear within a few days after birth. People with galactosemia frequently have symptoms as they grow older even though they have been given a galactose-free diet. These symptoms include **speech disorders**, cataracts, ovarian atrophy, and **infertility** in females, learning disabilities, and behavioral problems.

Galactosemia II

Galactosemia II is caused by defects in both copies of the gene that codes for an enzyme called galactokinase (GALK). The frequency of occurrence of galactosemia II is about one in 100,000–155,000 births.

Galactosemia II is less harmful than galactosemia I. Babies born with galactosemia II will develop cataracts at an early age unless they are given a galactose-free diet. They do not generally suffer from liver damage or neurologic disturbances.

Galactosemia III

Galactosemia III is caused by defects in the gene that codes for an enzyme called uridyl diphosphogalactose-4-epimerase (GALE). This form of galactosemia is very rare.

There are two forms of galactosemia III, a severe form, which is exceedingly rare, and a benign form. The benign form has no symptoms and requires no special diet. However, newborns with galactosemia III, including the benign form, have high levels of galactose-1-phosphate that show up on the initial screenings for elevated galactose and galactose-1-phosphate. This

WWW.BOOKBAZ.IR

situation illustrates one aspect of the importance of follow-up enzyme function tests. Tests showing normal levels of GALT and GALK allow people affected by the benign form of galactosemia III to enjoy a normal diet.

The severe form has symptoms similar to those of galactosemia I, but with more severe neurological problems, including seizures. Only two cases of this rare form has been reported.

Diagnosis

The newborn screening test for classic galactosemia is quick and straightforward; all but three states require testing on all newborns. Blood from a baby who is two to three days old is usually first screened for high levels of galactose and galactose-1-phosphate. If either of these compounds is elevated, further tests are performed to find out which enzymes (GALT, GALK, or GALE) are present or missing. DNA testing may also be performed to confirm the diagnosis.

If there is a strong suspicion that a baby has galactosemia, galactose is removed from the diet right away. In this case, an initial screen for galactose or galactose-1-phosphate will be meaningless. In the absence of galactose in the diet, this test will be negative whether the baby has galactosemia or not. In this case, tests to measure enzyme levels must be given to find out if the suspected baby is indeed galactosemic.

In addition, galactosemic babies who are refusing milk or vomiting will not have elevated levels of galactose or galactose phosphate, and their condition will not be detected by the initial screen. Any baby with symptoms of galactosemia (for example, vomiting) should be given enzyme tests.

Treatment

Galactosemia I and II are treated by removing galactose from the diet. Since galactose is a breakdown product of lactose, the primary sugar constituent of milk, this means all milk and foods containing milk products must be totally eliminated. Other foods like legumes, organ meats, and processed meats also contain considerable galactose and must be avoided. Pills that use lactose as a filler must also be avoided. Soy-based and casein hydrolysate-based formulas are recommended for infants with galactosemia.

Treatment of the severe form of galactosemia III with a galactose-restricted diet has been tried, but this disorder is so rare that the long-term effects of this treatment are unknown.

KEY TERMS

Casein hydrolysate—A preparation made from the milk protein casein, which is hydrolyzed to break it down into its constituent amino acids. Amino acids are the building blocks of proteins.

Catalyst—A substance that changes the rate of a chemical reaction, but is not physically changed by the process.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Galactose—One of the two simple sugars, together with glucose, that makes up the protein, lactose, found in milk. Galactose can be toxic in high levels.

Glucose—One of the two simple sugars, together with galactose, that makes up the protein, lactose, found in milk. Glucose is the form of sugar that is usable by the body to generate energy.

Lactose—A sugar made up of of glucose and galactose. It is the primary sugar in milk.

Metabolic pathway—A sequence of chemical reactions that lead from some precursor to a product, where the product of each step in the series is the starting material for the next step.

Metabolism—The total combination of all of the chemical processes that occur within cells and tissues of a living body.

Recessive trait—An inherited trait or characteristic that is outwardly obvious only when two copies of the gene for that trait are present.

Prognosis

Early detection in the newborn period is the key to controlling symptoms. Long-term effects in untreated babies include severe intellectual disabilities (ID), **cirrhosis** of the liver, and death. About 75% of the untreated babies die within the first two weeks of life. On the other hand, with treatment, a significant proportion of people with galactosemia I can lead nearly normal lives, although speech defects, learning disabilities, and behavioral problems are common. A 2004 study revealed that children and adolescents with classic galactosemia often have lower quality of life than peers without the disease, exhibiting problems with cognition (thinking and intellectual skills) and social function. In addition, cataracts due to galactosemia II can be completely prevented by a galactose-free diet.

Prevention

Since galactosemia is a recessive genetic disease, the disease is usually detected on a newborn screening test, since most people are unaware that they are carriers of a gene mutation causing the disease. For couples with a previous child with galactosemia, prenatal diagnosis is available to determine whether a pregnancy is similarly affected. Families in which a child has been diagnosed with galactosemia can have DNA testing which can enable other more distant relatives to determine their carrier status. Prospective parents can then use that information to conduct family planning or to prepare for a child with special circumstances. Children born with galactosemia should be put on a special diet right away, to reduce the symptoms and complications of the disease.

Gallbladder cancer

Definition

Cancer of the gallbladder is cancer of the pear-shaped organ that lies on the undersurface of the liver. The basic function of the gallbladder is to store bile, a fluid produced by the liver that is essential in the proper digestion of fats. The gallbladder in adult humans is about 3.1–4 inches long and 1.6 inches in diameter when it is completely filled.

Description

The human gallbladder serves primarily as a storage vessel for bile, a yellowish-brown or dark green fluid that aids in the digestion of fats in the small intestine. The gallbladder is not, however, essential to life and can be surgically removed when needed to treat recurrent gallstones or other disorders. Bile from the liver is funneled into the gallbladder by way of the cystic duct. Between meals, the gallbladder stores a large amount of bile. To do this, it must absorb much of the water and electrolytes from the bile. In fact, the inner surface of the gallbladder is the most absorptive surface in the body. After a meal, the gallbladder's muscular walls contract to deliver the bile back through the cystic duct and eventually into the small intestine, where the bile can help digest fatty foods.

Demographics

Gallbladder cancer is relatively uncommon compared to other cancers. About 10,650 new cases of gallbladder cancer will be diagnosed in the United States in 2014, making it the sixth most common gastrointestinal cancer; about 3,630 of these patients will die during the year. It is two to six times more common in females than males; and most patients are elderly. The average age of patients with gallbladder cancer in the United States and Canada is 72, and the risk increases with age. Southwest American Indians have a particularly high incidence—six times that of the general American population. Other high-risk populations include American Hispanics and people from Southeast Asia.

Causes and symptoms

Although the basic cause of gallbladder cancer is not well understood as of 2014, chronic inflammation plays an important role. Gallstones are the most significant risk factor in the development of gallbladder cancer. Roughly 75 to 90 percent of patients with gallbladder cancer also have gallstones. Larger gallstones are associated with a higher chance of developing gallbladder cancer. Chronic inflammation of the gallbladder from infection or parasitic infestation also increases the risk of gallbladder cancer.

Other risk factors include:

- Family history of gallbladder cancer.
- Obesity.

WWW.BOOKBAZ.IR

- History of heavy smoking.
- Congenital abnormalities in the structure of the gallbladder.
- Porcelain gallbladder. This is a condition in which calcium is deposited in the gallbladder wall, causing the organ to become bluish-white in appearance and brittle.
- In women, a high number of pregnancies.
- In men, Korean ethnicity.

Unfortunately, sometimes cancer of the gallbladder does not produce symptoms until late in the disease; this is one reason for the high mortality rate of this type of cancer in its later stages. When symptoms are evident, the most common is pain in the upper right portion of the abdomen, underneath the right ribcage. Patients with gallbladder cancer may also report such symptoms as nausea, vomiting, weakness, jaundice, skin itching, fever, chills, poor appetite, black or tarry stools, and weight loss. In some cases, the patient's gallbladder may become so enlarged that the physician can feel it during an examination of the abdomen.

Diagnosis

Diagnosis of gallbladder cancer is difficult because it mimics such other more common conditions as gallstones, cholecystitis, and pancreatitis. The imaging tests that are utilized to evaluate these other conditions, however, can also detect gallbladder cancer. For example, ultrasound is a quick, noninvasive imaging test that reliably diagnoses gallstones and cholecystitis. It can also detect the presence of gallbladder cancer as well as show how far the cancer has spread. If cancer is suspected, a computed tomography scan is useful in confirming the presence of an abnormal mass and further demonstrating the size and extent of the tumor. The wide variation in appearance of gallbladder tumors on CT scans, however, complicates the use of this imaging modality as a diagnostic tool; some gallbladder cancers appear as a general thickening of the wall of the organ rather than a well-defined mass. Cholangiography, usually performed to evaluate a patient with jaundice, can also detect gallbladder cancer.

There are no specific laboratory tests for gallbladder cancer as of 2014, although researchers are testing two tumor markers, CA242 and CA199, as possible screening tools. Other tumor markers that are presently used are CEA and CA 19-9, although these are not specific for gallbladder cancer. Blood tests are sometimes useful because tumors in the gallbladder can obstruct the normal flow of bile from the liver to the small intestine. Bilirubin, a component of bile, builds up within the liver and is absorbed into the bloodstream in excess amounts. This can be detected in a blood test, but it can also manifest clinically as jaundice. Elevated bilirubin levels and clinical jaundice can also occur with other conditions, such as gallstones.

On occasion, gallbladder cancer is diagnosed incidentally. About 1% of all patients who have their gallbladder removed for symptomatic gallstones are found to have gallbladder cancer. The cancer is found either by the surgeon or by the pathologist who inspects the gallbladder with a microscope.

Treatment

About 90% of gallbladder cancers are adenocarcinomas, which means that they are a type of cancer that begins in the gland-like cells that line the interiors of such organs as the gallbladder. The remaining 10% are sarcomas or squamous cell carcinomas.

Staging of gallbladder cancer is determined by how far the cancer has spread. The effectiveness of treatment declines as the stage progresses. Most gallbladder cancers begin in the innermost wall of the organ and grow through the various layers of tissue toward the outside of the gallbladder. Stage 0 gallbladder cancer is very small and confined to the inner wall of the gallbladder. Approximately 20% of cancers are at this stage at the time of diagnosis; the 5-year survival rate is 80%. Stage I cancer has grown into the intermediate walls of the organ; its 5-year survival rate is 50%. Stage II cancer has penetrated the full thickness of the wall, but has not spread to nearby lymph nodes or invaded adjacent organs; its 5-year survival rate is 28%. Stage III cancer has spread to nearby lymph nodes or has invaded the liver, stomach, colon, small intestine, or large intestine; its 5-year survival rate is 7–8%. Stage IV disease has invaded very deeply into two or more adjacent organs, has grown into the main blood vessels leading into the liver, or has spread to distant lymph nodes or organs by way of metastasis; its 5-year survival rate is 2–4%.

Early Stage I cancers involving only the innermost layer of the gallbladder wall can be cured by simple removal of the gallbladder; this procedure is called a cholecystectomy. Cancers at this stage are sometimes found incidentally when the gallbladder is removed in the treatment of gallstones or cholecystitis. Late Stage I cancers, which involve the outer muscular layers of the gallbladder wall, are generally treated in the same way as Stage II or III cancers. Removal of the gallbladder is not sufficient for these stages. The surgeon also removes nearby lymph nodes as well as a portion of the adjacent liver; this is called an extended or radical cholecystectomy. Patients with early Stage IV

KEY TERMS

Adenocarcinoma—A type of cancerous tumor that develops in the gland-like cells of epithelial tissue, which is the tissue that lines the inner and exterior surfaces of body organs.

Cholangiography—Radiographic examination of the bile ducts after injection with a special dye. It is used to determine whether the bile ducts are enlarged, narrowed, or blocked.

Cholecystectomy—The medical term for surgical removal of the gallbladder.

Cholecystitis—Inflammation of the gallbladder, usually due to infection

Computed tomography—A radiology test by which images of cross-sectional planes of the body are obtained

Congenital—Present at birth.

Jaundice—Yellowish staining of the skin and eyes due to excess bilirubin in the bloodstream

Metastasis (plural, metastases)—The spread of tumor cells from one part of the body to another through blood vessels or lymphatic vessels

Pancreatitis—Inflammation of the pancreas

Porcelain gallbladder—A condition in which calcium is deposited in the walls of the gallbladder, causing the organ to become whitish or bluish-white in appearance and brittle.

Resection—The surgical removal of an organ or part of an organ.

Stent—Slender hollow catheter or rod placed within a vessel or duct to provide support or maintain patency

Tumor marker—A protein found in blood, urine, or body tissues that can be measured and used to detect the presence of cancer.

Ultrasound—A radiology test utilizing high-frequency sound waves

disease may benefit from radical surgery, but the issue is controversial. Late Stage IV cancer has spread too extensively to allow complete resection. Surgery is not an option for these patients.

Other therapies

When long-term survival is not likely, the focus of therapy shifts to improving quality of life. Jaundice and blockage of the stomach are two problems faced by patients with advanced cancer of the gallbladder. These can be treated with surgery, or alternatively, by special interventional techniques employed by the gastroenterologist or radiologist. A stent can be placed across the bile ducts in order to re-establish the flow of bile and relieve jaundice. A small feeding tube can be placed in the small intestine to allow feeding when the stomach is blocked. Pain may be treated with conventional pain medicines or a celiac ganglion nerve block. Another palliative treatment that is sometimes used to relieve pain in gallbladder cancer is alcohol injections to deaden the nerves that carry pain sensations from the gallbladder and digestive tract to the brain.

Current chemotherapy or radiation therapy cannot cure gallbladder cancer, but these modalities may offer some benefit in certain patients. For cancer that is too advanced for surgical cure, treatment with such chemotherapeutic agents as 5-fluorouracil, gemcitabine, cisplatin, or capecitabine may lengthen survival for a few months. The limited benefit of chemotherapy must be weighed carefully against its side effects. Radiation therapy is sometimes used after attempted surgical resection of the cancer to extend survival for a few months or relieve jaundice. The most common form of radiation therapy used to treat gallbladder cancer is external beam radiation therapy. Radiation therapy may be used as a palliative treatment to relieve pain in patients with advanced gallbladder cancer.

Complementary and alternative (CAM) treatments cannot cure gallbladder cancer but may be helpful in relieving the emotional and spiritual distress of patients with this type of cancer. Acupuncture is reported to relieve nausea associated with chemotherapy, and essential oils used in aromatherapy (particularly lavender and Roman chamomile) are calming and relaxing for some patients. Prayer, meditation, journaling or expressive writing, and guided imagery are helpful for others.

Gallbladder disease *see* **Cholecystitis**

Gallbladder nuclear medicine scan

Definition

A nuclear medicine scan of the gallbladder is used to produce a set of images that look like x rays. The procedure uses a small amount of radioactive dye which is injected into the body. The dye accumulates in the organ, in this case, the gallbladder. A special camera called a scintillation or gamma camera produces images based on how the dye travels through the system and how the radiation is absorbed by the tissues. The procedure is also called cholescintigraphy or a hepatobiliary scan.

Purpose

A nuclear medicine scan can be used to diagnose disease and to find abnormalities in a body organ. A gallbladder scan can detect **gallstones**, tumors, or defects of the gallbladder. It can also be used to diagnose blockages of the bile duct that leads from the gallbladder to the small intestine. Unlike **ultrasound**, a gallbladder nuclear medicine scan can assess gallbladder function.

Precautions

Women who are pregnant or **breastfeeding** should tell their doctors before a scan is performed. Some medications or even eating a high fat meal before the procedure can interfere with the results of the scan.

Description

The gallbladder is a small pear-shaped sac located under the liver. The liver produces bile, a yellowish-green mixture of salts, acids, and other chemicals, that are stored in the gallbladder. Bile is secreted into the small intestine to help the body digest fats from foods.

Gallbladder disease, gallstones, cancer, or other abnormalities can cause **pain** and other symptoms. A gallbladder condition might be suspected if a patient has chronic or occasional pain in the upper right side of the abdomen. The pain may be stabbing and intense with sudden onset or it may be more of a dull, occasional ache. Loss of appetite, **nausea and vomiting** can also occur. **Fever** may indicate the presence of infection. **Jaundice**, a yellowing of the skin and whites of the eyes, may also indicate that the gallbladder is involved.

KEY TERMS

Cholecystitis—Inflammation of the gallbladder.

Cholescintigraphy—Another term for a gallbladder nuclear medicine scan.

Hepatobiliary scan—Another term for a gallbladder nuclear medicine scan.

Scintillation or gamma camera—A camera, somewhat like an x-ray machine, used to photograph internal organs after the patient has been injected with a radioactive material.

A gallbladder nuclear medicine scan may be used to diagnose gallstones, blockage of the bile duct or other abnormalities, and to assess gallbladder functioning and inflammation (**cholecystitis**). The scan is usually performed in a hospital or clinical **radiology** department. The patient lies on an examination table while a small amount of radioactive dye is injected into a vein in the arm. This dye circulates through the blood and collects in the gallbladder. As the dye moves through the gallbladder, a series of pictures is taken using a special camera called a *scintillation* or *gamma camera*. This procedure produces images that look like x rays. The test usually takes one to two hours to complete, but can last up to four hours.

The results of the scan are read by a radiologist, a doctor specializing in x rays and other types of scanning techniques. A report is sent, usually within 24 hours, to the doctor who will discuss the results with the patient.

Preparation

The patient may be required to withhold food and liquids for up to eight hours before the scan.

Aftercare

No special care is required after the procedure. Once the scan is complete, the patient can return to normal activities.

Results

A normal scan shows a gallbladder without gallstones. There will be no evidence of growths or tumors, and no signs of infection or swelling. The normal gallbladder fills with bile and secretes it through the bile duct without blockages.

Abnormal

An abnormal scan may show abnormal gallbladder emptying (suggesting gallbladder dysfunction or inflammation), or gallstones in the gallbladder or in the bile duct. The presence of tumors, growths or other types of blockages of the duct or the gallbladder itself could also appear on an abnormal scan.

Risks

Nuclear medicine scans use a very small amount of radioactive material, and the risk of radiation is minimal. Very rarely, a patient may have a reaction to the dye material used.

Gallbladder surgery *see* **Cholecystectomy**

Gallbladder x rays

Definition

This is an x-ray exam of the gallbladder (GB), a sac-like organ that stores bile that is located under the liver. The study involves taking tablets containing dye (contrast) which outline any abnormalities when x rays are taken the following day. The test was once the standard for diagnosing diseases of the GB such as **gallstones**, but is used less frequently now. This is due to advances in diagnostic **ultrasound**, which is quick, accurate, and does not involve exposure to ionizing radiation. When functional parameters of the gallbladder need to be demonstrated, scintigraphy is now the study of choice. Oral cholecystogram (OCG), however, can be useful when a gallbladder is contracted down due to the presence of many, many gallstones. It can also help determine whether the cystic duct is clear, prior to surgical procedures such as **lithotripsy**. OCG may also be used to evaluate gallbladder disease that does not involve gallstones, such as adenomyomatosis of the gallbladder or cholesterolosis of the gallbladder. Both ultrasound and OCG can detect gallstones in the gallbladder about 95% of the time.

WWW.BOOKBAZ.IR

Description

The exam is performed in the **radiology** department. The night before the test, patients swallow six tablets (one at a time) that contain the contrast (x-ray dye). The following day at the hospital, the radiologist examines the gallbladder with a fluoroscope (a special x ray that projects the image onto a video monitor). Sometimes, patients are then asked to drink a high-fat formula that will cause the gallbladder to contract and release bile. X rays will then be taken at various intervals. There is no discomfort from the test. If the gallbladder is not seen, the patient may be asked to return the following day for x rays.

Purpose

The OCG test is usually ordered to help physicians diagnose disorders of the gallbladder, such as gallstones and tumors, which show up as solid dark structures. It is performed to help in the investigation of patients with upper abdominal **pain**. The test also measures gallbladder function, as the failure of the organ to visualize can signify a nonfunctioning or diseased gallbladder. The gallbladder may also not visualize if the bilirubin level is over 4 and the study should not be performed under these circumstances.

Precautions

A physician must be notified if individuals are pregnant or allergic to iodine. Patients with a history of severe kidney damage, have an increased risk of injury or side effects from the procedure. In those cases, ultrasound is commonly used instead of the x-ray examination. Some people experience side effects from the contrast material (dye tablets), especially **diarrhea**. During preparation for the test, patients should not use any **laxatives**. People with diabetes should discuss the need for any adjustment in medication with their physician.

Preparation

The day before the test patients are instructed to eat a high fat lunch (eggs, butter, milk, salad oils, or fatty meats), and a fat-free meal (fruits, vegetables, bread, tea or coffee, and only lean meat) in the evening. Two hours after the evening meal, six tablets containing the contrast medium, are taken, one a time. After that, no food or fluid is permitted until after the test.

KEY TERMS

Bile—A yellow-green liquid produced by the liver, which is released through the bile ducts into the small intestines to help digest fat.

Bilirubin—A reddish-yellow pigment formed from the destruction of red blood cells, and metabolized by the liver. Levels of bilirubin in the blood increase in patients with liver disease or blockage of the bile ducts.

Gallstone—Hardened deposits of digestive fluid that can form in your gallbladder.

Ultrasound—A non-invasive procedure based on changes in sound waves of a frequency that cannot be heard, but respond to changes in tissue composition. It requires no preparation and no radiation occurs; it has become the "gold standard" for diagnosis of stones in the gallbladder, but is less accurate in diagnosing stones in the bile ducts. Gallstones as small as 2 mm can be identified.

Aftercare

No special care is required after the study.

Results

With normal results, the x ray will show normal structures for the age of the patient. The gallbladder should visualize, and be free of any solid structures, such as stones, polyps, etc.

Abnormal results may show gallstones, tumors, or **cholesterol** polyps (a tumor growing from the lining that is usually noncancerous). Typically stones will "float" or move around as the patient changes position, whereas tumors will stay in the same place.

Risks

There is a small chance of an allergic reaction to the contrast material. In addition, there is low radiation exposure. X rays are monitored and regulated to provide the minimum amount of radiation exposure needed to produce the image. Most experts feel that the risk is low compared with the benefits. Pregnant women and children are more sensitive to the risks of x rays, and the risk versus benefits should be discussed with the treating physician.

Gallium scan

Definition

A **gallium scan** is a nuclear medicine test that is conducted using a camera that detects gallium, a form of radionuclide, or radioactive chemical substance.

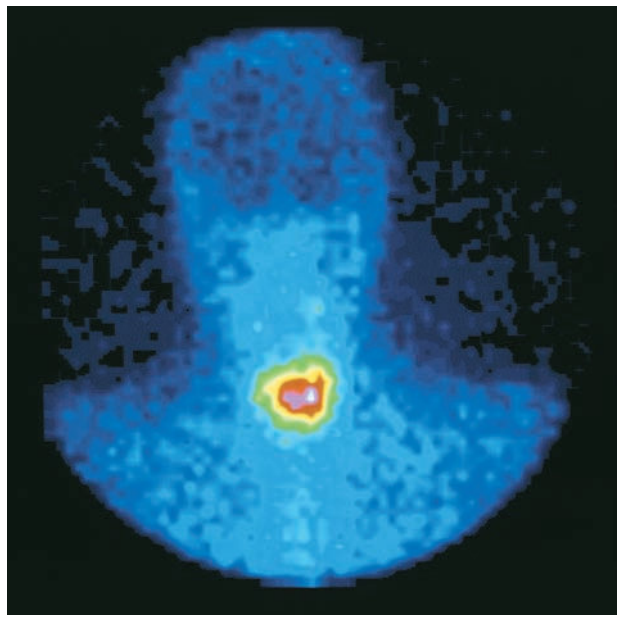
Description

The patient is usually be asked to come to the testing facility 24–48 hours before the procedure to receive the injection of gallium. Sometimes, the injection will be given only four to six hours before the study or as long as 72 hours before the procedure. The timeframe is based on the area or organs of the body being studied.

For the study itself the patient lies very still for approximately 30–60 minutes. A camera is moved across the patient's body to detect and capture images of concentrations of the gallium. The camera picks up signals from all accumulations of the radionuclide. In most cases, the patient is lying down throughout the procedure. Back (posterior) and front (anterior) views are usually taken, and sometimes a side (lateral) view is used. The camera may occasionally touch the patient's skin but will not cause any discomfort. A clicking noise may be heard throughout the procedure; this is only the sound of the scanner registering radiation.

Purpose

Most gallium scans are ordered to detect cancerous tumors, infections, or areas of swelling or inflammation in the body. The test is also used to monitor the response of antibiotic treatment. Gallium is known to accumulate in inflamed, infected, or cancerous tissues.



Gallium scan highlighting the thyroid gland. *(Photo Researchers, Inc.)*

The scans are used to determine whether a patient with an unexplained **fever** has an infection and the site of the infection, if present. Gallium scans also may be used to evaluate cancer following **chemotherapy** or **radiation therapy**.

Preparation

The intravenous injection of gallium is done in a separate appointment prior to the procedure. Generally, no special dietary requirements are necessary. Sometimes the physician will ask that the patient have light or clear meals within a day or less of the procedure. Many patients will be given **laxatives** or an enema prior to the scan to eliminate any residual gallium from the bowels.

Aftercare

There is generally no aftercare required following a gallium scan. However, women who are **breastfeeding** who have a scan will be cautioned against breastfeeding for four weeks following the exam.

Risks

There is a minimal risk of exposure to radiation from the gallium injection, but the exposure from one gallium scan is generally less than exposure from x rays. Sometimes a patient may have soreness or swelling in the injection area.

WWW.BOOKBAZ.IR

KEY TERMS

Benign—Not cancerous. Benign tumors are not considered immediate threats but may still require some form of treatment.

Gallium—A form of radionuclide that is used to help locate tumors and inflammation (specifically referred to as GA67 citrate).

Malignant—Used to describe a tumor that is cancerous.

Nuclear medicine—A subspecialty of radiology used to show the function and anatomy of body organs. Very small amounts of radioactive substances, or tracers, are detected with a special camera as they accumulate in certain organs and tissues.

Radionuclide—A chemical substance, called an isotope, that exhibits radioactivity. A gamma camera, used in nuclear medicine procedures, will pick up the radioactive signals as the substance gathers in an organ or tissue. They are sometimes referred to as tracers.

Gallstone removal

Definition

Also known as cholelithotomy, gallstone removal is a procedure that rids the gallbladder of calculus buildup. **Gallstones** are hardened deposits of digestive fluid that sometimes form in the pear-shaped organ called the gallbladder, which is located on the right side of the abdomen, just below the liver.

Purpose

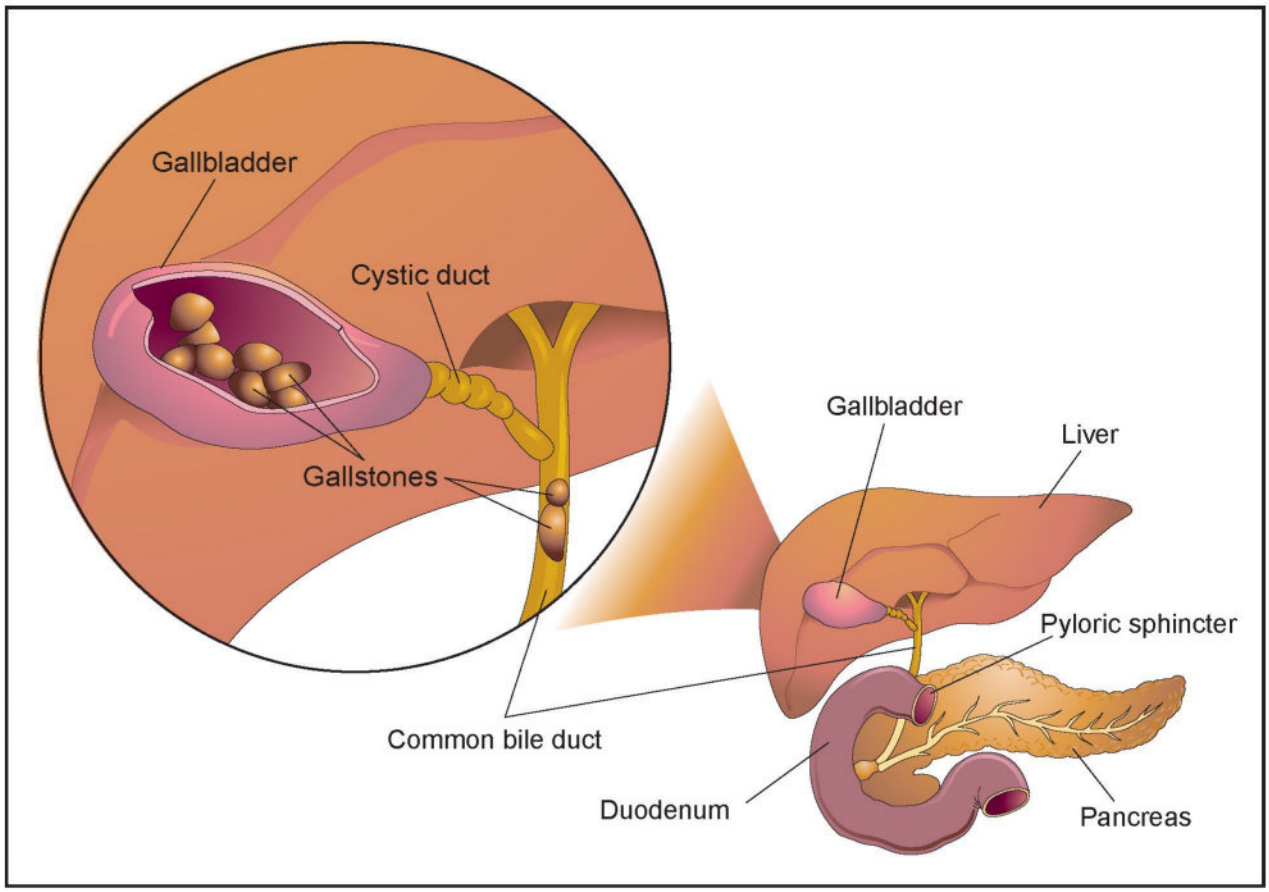
The gallbladder is not a vital organ. It is located on the right side of the abdomen underneath the liver. The gallbladder's function is to store bile, concentrate it, and release it during digestion. Bile is supposed to retain all of its chemicals in solution, but commonly one of them crystallizes and forms sandy or gravel-like particles, finally collecting into gallstones, which range in size from as small as a grain of sand to as large as a golf ball. The formation of gallstones causes gallbladder disease (cholelithiasis).

Chemicals in bile will form crystals as the gallbladder draws water out of the bile. The solubility of these chemicals is based on the concentration of three chemicals: bile acids, phospholipids, and **cholesterol**. If the chemicals are out of balance, one or the other will not remain in solution. Supersaturation of dietary fat and cholesterol are also implicated in crystal formation.

As the bile crystals aggregate to form stones, they move about, eventually blocking the outlet and preventing the gallbladder from emptying. This blockage results in irritation, inflammation, and sometimes infection (**cholecystitis**) of the gallbladder. The pattern is usually one of intermittent obstruction due to stones moving in and out of the way. Meanwhile, the gallbladder becomes more and more scarred. Sometimes, infection leads to pus formation in the gallbladder with pus, which is a serious complication.

Occasionally, a gallstone will travel down the cystic duct into the common bile duct and get stuck. This blockage will back bile up into the liver as well as the gallbladder. If the stone obstructs the ampulla of Vater (a narrow mouth in the duct leading to the pancreas), the pancreas will also be blocked and will develop **pancreatitis**.

Gallstones will cause a sudden onset of **pain** in the upper abdomen. Pain will last for 30 minutes to several hours. Pain may move to the right shoulder blade. Nausea with or without **vomiting** may accompany the pain.



Gallstone removal, also known as cholelithotomy, usually involves the surgical removal of the entire gallbladder, but in recent years the procedure done by laparoscopy has resulted in smaller surgical incisions and faster recovery time. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Treatment for gallstones is usually not necessary if they do not cause pain or other symptoms. However, if symptoms occur, then consultation with a medical professional is necessary to decide on the best option for their removal. Mild pain usually means that surgery does not need to be performed immediately. When severe pain in present then surgery is usually required as soon as possible to prevent future attacks and complications. According to WebMD, "... in most cases the best treatment is surgery to remove the gallbladder (**cholecystectomy**). In many cases, laparoscopic surgery is the best method to remove the gallbladder. Open surgery results in a longer recovery period and causes more pain because it requires a larger incision."

Demographics

Gallstones are approximately two times more common in females than in males. Overweight women in their middle years constitute the vast majority of patients with gallstones in every racial or ethnic group. An estimated 10% of the general population has gallstones. The prevalence for women between ages 20 and 55 is about 20%, and is higher after age 50 (25–30%). Women between the ages of 20 and 60 years are three times more likely to have gallstones than are men. Certain people, in particular the Pima tribe of Native Americans in Arizona, have a genetic predisposition to forming gallstones. Scandinavians also have a higher than average incidence of this disease.

There seems to be a strong genetic correlation with gallstone disease, because stones are more than four times as likely to occur among first-degree relatives. Since gallstones rarely dissolve spontaneously, the prevalence increases with age. **Obesity** is a well-known risk factor since being overweight causes chemical abnormalities that lead to increased levels of cholesterol. Gallstones are also associated with rapid weight loss secondary to dieting. **Pregnancy** is a risk factor since increased estrogen levels result in an increased cholesterol secretion and abnormal changes in bile. However, while an increase in dietary

WWW.BOOKBAZ.IR

cholesterol is not a risk factor, an increase in **triglycerides** is positively associated with a higher incidence of gallstones. **Diabetes mellitus** is also believed to be a risk factor for gallstone development.

Description

The procedure is performed in a hospital by a physician who specializes in **general surgery** and has extensive experience in the surgical techniques required.

Surgery to remove the entire gallbladder with all its stones is usually the best treatment, provided the patient is able to tolerate the procedure. A relatively new technique of removing the gallbladder using a laparoscope has resulted in quicker recovery and much smaller surgical incisions than the 6 in (15 cm) gash under the ribs on the right that had previously been the standard procedure; however, not everyone is a candidate for this approach. If the procedure is not expected to have complications, laparoscopic cholecystectomy is performed. Laparoscopic surgery requires a space in the surgical area for visualization and instrument manipulation. The laparoscope with attached video camera is inserted. Several other instruments are inserted through the abdomen to assist the surgeon to maneuver around other nearby organs during surgery. The surgeon must take precautions not to accidentally harm anatomical structures in the liver. Once the cystic artery has been divided and the gallbladder dissected from the liver, the gallbladder can be removed.

Several centers are now offering single-site cholecystectomy, which is done with one single small incision through which all of the laparoscopic instruments enter the body. It is more challenging, but has a better cosmetic outcome.

If the gallbladder is extremely diseased (inflamed, infected, or has large gallstones), the abdominal approach (open cholecystectomy) is recommended. This surgery is usually performed with an incision in the upper midline of the abdomen or on the right side of the abdomen below the rib (right subcostal incision).

If a stone is lodged in the bile ducts, additional surgery must be done to remove it. After surgery, the surgeon will ordinarily insert a drain to collect bile until the system is healed. The drain can also be used to inject contrast material and take x rays during or after surgery.

A procedure called endoscopic retrograde cholangiopancreatoscopy (ERCP) allows the removal of some bile duct stones through the mouth, throat, esophagus, stomach, duodenum, and biliary system without the need for surgical incisions. ERCP can also be used to inject contrast agents into the biliary system, providing finely detailed pictures.

Patients with symptomatic cholelithiasis can be treated with certain medications, a technique called oral bile acid litholysis or oral dissolution therapy. This technique is especially effective for dissolving small cholesterol-composed gallstones. Current research indicates that the success rate for oral dissolution treatment is 70–80% with floating stones (those predominantly composed of cholesterol). Approximately 10–20% of patients who receive medication-induced litholysis can have a recurrence within the first two or three years after treatment completion.

Extracorporeal shock wave **lithotripsy** (ESWL) is a treatment in which shock waves are generated in water by lithotripters (devices that produce the waves). There are several types of lithotripters available for gallbladder removal. One specific lithotripter involves the use of piezoelectric crystals, which allow the shock waves to be accurately focused on a small area to disrupt a stone. This procedure does not generally require analgesia (or **anesthesia**). Damage to the gallbladder and associated structures (such as the cystic duct) must be present for stone removal after the shock waves break up the stone. Typically, repeated shock wave treatments are necessary to completely remove gallstones. The success rate of the fragmentation of the gallstone and urinary clearance is inversely proportional to stone size and number: patients with a small solitary stone have the best outcome, with high rates of stone clearance (95% are cleared within 12–18 months), while patients with multiple stones are at risk for poor clearance rates. Complications of shock wave lithotripsy include inflammation of the pancreas (pancreatitis) and acute cholecystitis. Gallstones do recur after lithotripsy; the rate of recurrence after the first year is 6–7%, and after five years the rate of recurrence is 31–44%.

A method called contact dissolution of gallstone removal involves direct entry (via a percutaneous transhepatic catheter) of a chemical solvent such as methyl tert-butyl ether (MTBE). MTBE is rapidly removed from the body via the respiratory system (exhaled air). Side effects in persons receiving contact dissolution therapy include foul-smelling breath, dyspnea (difficulty breathing), vomiting, and drowsiness. Treatment with MTBE can be successful in treating cholesterol gallstones regardless of the number and size of stones. Studies indicate that the success rate for dissolution is well over 95% in persons who receive direct chemical infusions that can last 5–12 hours.

Diagnosis

Diagnostically, gallstone disease, which can lead to gallbladder removal, is divided into four diseases: biliary **colic**, acute cholecystitis, choledocholithiasis, and **cholangitis**. Biliary colic is usually caused by intermittent cystic duct obstruction by a stone (without any inflammation), causing a severe, poorly localized, and intensifying pain on the upper right side of the abdomen. These painful attacks can persist from days to months in patients with biliary colic.

Persons affected with acute cholecystitis caused by an impacted stone in the cystic duct also suffer from gallbladder infection in approximately 50% of cases. These people have moderately severe pain in the upper right portion of the abdomen that lasts longer than six hours. Pain with acute cholecystitis can also extend to the shoulder or back. Since there may be infection inside the gallbladder, the patient may also have **fever**. On the right side of the abdomen below the last rib, there is usually tenderness with inspiratory (breathing in) arrest (Murphy's sign). In about 33% of cases of acute cholecystitis, the gallbladder may be felt in the abdomen with palpation (feeling for tenderness). Mild **jaundice** can be present in about 20% of cases.

Persons with choledocholithiasis, or intermittent obstruction of the common bile duct, often do not have symptoms, but if present they are indistinguishable from the symptoms of biliary colic.

A more severe form of gallstone disease is cholangitis, which causes stone impaction in the common bile duct. In about 70% of cases, these patients present with Charcot's triad (pain, jaundice, and fever). Patients with cholangitis may have chills, mild pain, lethargy, and **delirium**, which indicate that infection has spread to the bloodstream (**bacteremia**). The majority of patients with cholangitis will have fever (95%), tenderness in the upper right side of the abdomen, and jaundice (80%).

The most common symptom of gallstones is pain in the stomach, in the upper-right portion of the belly, and under the ribs. It may prevent the taking of normal or deep breaths, and may last a few minutes or many hours. Continuous pain from gallstones may occur. Other symptoms include:

- dark urine
- fever and chills
- light-colored stools
- loss of appetite
- nausea
- yellowing of the skin and the white part of the eyes
- vomiting

Other medical problems can also produce similar symptoms, so it is always advisable to seek medical help when these symptoms occur.

Preparation

In addition to a **physical examination**, preparation for laboratory (blood) and special tests is essential to gallstone diagnosis. Patients with biliary colic may have elevated bilirubin and should have an **ultrasound** study to visualize the gallbladder and associated structures. An increase in the **white blood cell count** (**leukocytosis**) can be expected for both acute cholecystitis and cholangitis (seen in 80% of cases). Ultrasound testing is recommended for acute cholecystitis patients, whereas ERCP is the test usually indicated to assist in a definitive diagnosis for both choledocholithiasis and cholangitis. Patients with either biliary colic or choledocholithiasis are treated with elective laparoscopic cholecystectomy. Open cholecystectomy is recommended for acute cholecystitis. For cholangitis, emergency ERCP is indicated for stone removal. ERCP therapy can remove stones produced by gallbladder disease.

Aftercare

Without a gallbladder, stones rarely recur. Patients who have continued symptoms after their gallbladder is removed may need an ERCP to detect residual stones or damage to the bile ducts caused by the original stones. Occasionally, the ampulla of Vater is too tight for bile to flow through and causes symptoms until it is opened up.

Results

Most patients undergoing laparoscopic cholecystectomy may go home the same day of surgery, and may immediately return to normal activities and a normal diet, while most patients who undergo open cholecystectomy must remain in the hospital for five to seven days. After one week, they may resume a normal diet, and in four to six weeks they can expect to return to normal activities.

Morbidity and mortality rates

Cholecystectomy is generally a safe procedure, with an overall mortality rate of 0–1 per 1,000. Infections occur in less than 1 per 1,000 patients undergoing laparoscopic cholecystectomy. Heart problems during the procedures occur at a rate of 5 per 1,000 for **arrhythmias** and 1 per 1,000 for actual **heart attack**. Pregnant women who must undergo cholecystectomy

WWW.BOOKBAZ.IR

KEY TERMS

Bilirubin—A pigment released from red blood cells.

Cholecystectomy—Surgical removal of the gallbladder.

Cholelithotomy—Surgical incision into the gallbladder to remove stones.

Contrast agent—A substance that causes shadows on x rays (or other images of the body).

Cystic artery—An artery that brings oxygenated blood to the gallbladder.

Endoscope—An instrument designed to enter body cavities.

Jaundice—A yellow discoloration of the skin and eyes due to excess bile that is not removed by the liver.

Laparoscopy—Surgery performed through small incisions with pencil-sized instruments.

Triglycerides—Chemicals made up mostly of fat that can form deposits in tissues and cause health risks or disease.

have a high rate of fetal loss: 40 per 1,000 when no pancreatitis is present and as high as 600 per 1,000 when pancreatitis is present. The improved technique of laparoscopic cholecystectomy accounts for 90% of all cholecystectomies performed in the United States; the improved technique reduces time missed away from work, patient hospitalization, and postoperative pain.

Risks

The most common medical treatment for gallstones is the surgical removal of the gallbladder (cholecystectomy). Risks associated with gallbladder removal are low, but include damage to the bile ducts, residual gallstones in the bile ducts, or injury to the surrounding organs. With open cholecystectomy, bile duct damage occurs at a rate of 1 per 1,000 patients; for laparoscopic cholecystectomy, the bile duct damage rate is 1–5 per 1,000 patients.

Alternatives

There are no other acceptable alternatives for gallstone removal besides surgery, shock wave fragmentation, or chemical dissolution. However, the Mayo Clinic states two options to help reduce the risk of gallstone complications. One option is to eat a high-fiber diet that includes healthy fats (such as those found in fish and nuts) and a variety of fruits and vegetables. The other option is to take vitamin supplements regularly. Although medical evidence does not prove that supplements will prevent gallstones, people who do not receive sufficient amounts of vitamin C, **vitamin E**, or **calcium** in their diet may be at increased risk for gallstones.

Gallstones

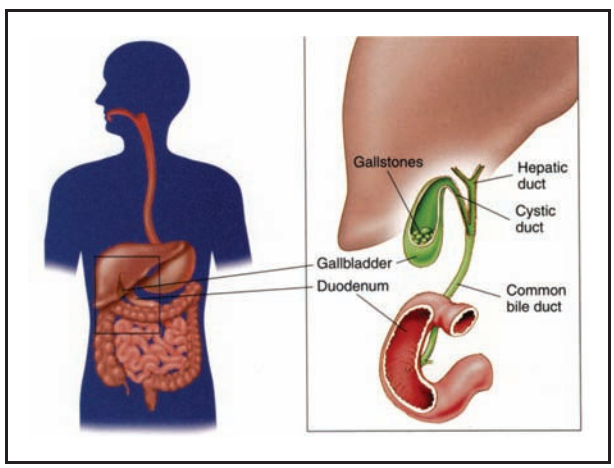
Definition

A gallstone is a solid crystal deposit that forms in the gallbladder, which is a pear-shaped organ that stores bile salts until they are needed to help digest fatty foods. Gallstones can migrate to other parts of the digestive tract and cause severe **pain** with life-threatening complications.

Demographics

Gallstones are the most common of all gallbladder problems. They are responsible for 90% of gallbladder and bile duct disease, and are the fifth most common reason for hospitalization of adults in the United States. Over half a million people per year in the United States develop symptoms of or complications from gallstones that require removal of the gallbladder.

Gallstones usually develop in adults between the ages of 20 and 50; about 20% of patients with gallstones are over 40. The risk of developing gallstones increases with age. At least 20% of people over 60 have a single large stone or as many as several thousand smaller ones. The gender ratio of gallstone patients changes with age. Young women are between two and six times as likely to develop gallstones as are men in the same age group. In patients over 50, the condition affects men and women with equal frequency. The lifetime risk for developing gallstones is 50% in women and about 30% in men. Mexican Americans and Native Americans develop gallstones more often than any other segment of the population.



Gallstones form in the gallbladder but can migrate to other parts of the body via the bile duct. *(Illustration by Frank Forney. © Cengage Learning®.)*

Description

Gallstones vary in size and chemical structure. A gallstone may be as tiny as a grain of sand or as large as a golf ball. Eighty percent of gallstones are composed of **cholesterol**. They are formed when the liver produces more cholesterol than digestive juices can liquefy. The remaining 20% of gallstones are composed of **calcium** and an orange-yellow waste product called bilirubin. Bilirubin gives urine its characteristic color and sometimes causes **jaundice**.

Risk factors

Some risk factors associated with the development of cholesterol gall stones include:

- female gender
- increasing age
- Mexican or Native American ancestry
- history of multiple pregnancies
- conditions which result in gallbladder stasis (decreased movement or flow of bile in the gallbladder) such as rapid weight loss and high spinal cord injuries

Women who take oral birth control pills containing estrogen, women using other estrogen-dispensing birth control devices, and some men who are prescribed estrogen and/or estrogen-like drugs for the treatment of **prostate cancer** are also at high risk. Up to 25% of people who develop gallstones develop the stones as a result of hereditary predisposition.

Definitions

Gallstones can cause several different disorders. Cholelithiasis is defined as the presence of gallstones within the gallbladder itself. Choledocholithiasis is the presence of gallstones within the common bile duct that leads into the first portion of the small intestine (the duodenum). The stones in the duct may have been formed inside it or carried there from the gallbladder. These gallstones prevent bile from flowing into the duodenum. Ten percent of patients with gallstones have choledocholithiasis, which is sometimes called common-duct stones. Patients who do not develop infection usually recover completely from this disorder.

Cholecystitis is a disorder marked by inflammation of the gallbladder. It is usually caused by the passage of a stone from the gallbladder into the cystic duct, which is a tube that connects the gallbladder to the common bile duct. In five to 10 percent of cases, however, cholecystitis develops in the absence of gallstones. This form of the disorder is called acalculous cholecystitis. Cholecystitis causes painful enlargement

WWW.BOOKBAZ.IR

of the gallbladder and is responsible for 10–25% of all gallbladder surgery. Chronic cholecystitis is most common in the elderly. The acute form is most likely to occur in middle-aged adults.

Cholesterolosis or cholesterol polyps is characterized by deposits of cholesterol crystals in the lining of the gallbladder. This condition may be caused by high levels of cholesterol or inadequate quantities of bile salts, and is usually treated by surgery.

Gallstone **ileus**, which results from a gallstone's blocking the entrance to the large intestine, is most common in elderly people. Surgery usually cures this condition.

Narrowing (stricture) of the common bile duct develops in as many as five percent of patients whose gallbladders have been surgically removed. This condition is characterized by inability to digest fatty foods and by abdominal pain, which sometimes occurs in spasms. Patients with stricture of the common bile duct are likely to recover after appropriate surgical treatment.

KEY TERMS

Acalculous cholecystitis—Inflammation of the gallbladder that occurs without the presence of gallstones.

Bilirubin—A reddish-yellow waste product produced by the liver that colors urine and is involved in the formation of some gallstones.

Celiac disease—Inability to digest wheat protein (gluten), which causes weight loss, lack of energy, and pale, foul-smelling stools.

Cholecystectomy—Surgical removal of the gallbladder.

Cholecystitis—Inflammation of the gallbladder.

Choledocholithiasis—The presence of gallstones within the common bile duct.

Cholelithiasis—The presence of gallstones within the gallbladder.

Cholesterolosis—Cholesterol crystals or deposits in the lining of the gallbladder.

Common bile duct—The passage through which bile travels from the cystic duct to the small intestine.

Gallstone ileus—Obstruction of the large intestine caused by a gallstone that has blocked the intestinal opening.

Lithotripsy—A nonsurgical technique for removing gallstones by breaking them apart with high-frequency sound waves.

Causes and symptoms

Gallstones are caused by an alteration in the chemical composition of bile. Bile is a digestive fluid that helps the body absorb fat. Gallstones tend to run in families. In addition, high levels of estrogen, insulin, or cholesterol can increase a person's risk of developing them.

Pregnancy or the use of birth control pills can slow down gallbladder activity and increase the risk of gallstones. So can diabetes, **pancreatitis**, and **celiac disease**. Other factors influencing gallstone formation are:

- infection
- obesity
- intestinal disorders
- coronary artery disease or other recent illness
- multiple pregnancies
- a high-fat, low-fiber diet
- smoking
- heavy drinking
- rapid weight loss

Gallbladder attacks usually follow a meal of rich, high-fat foods. The attacks often occur in the middle of the night, sometimes waking the patient with intense pain that ends in a visit to the emergency room. The pain of a gallbladder attack begins in the abdomen and may radiate to the chest, back, or the area between the shoulders. Other symptoms of gallstones include:

- inability to digest fatty foods
- low-grade fever
- chills and sweating
- nausea and vomiting
- indigestion
- gas
- belching
- clay-colored bowel movements

Diagnosis

Examination

Gallstones may be diagnosed by a family doctor, a specialist in digestive problems (a gastroenterologist), or a specialist in internal medicine. The doctor will first

examine the patient's skin for signs of jaundice and feel (palpate) the abdomen for soreness or swelling.

Tests

After the basic **physical examination**, the doctor will order blood counts or blood chemistry tests to detect evidence of bile duct obstruction and to rule out other illnesses that cause **fever** and pain, including stomach **ulcers**, **appendicitis**, and heart attacks.

Procedures

More sophisticated procedures used to diagnose gallstones include:

- Ultrasound imaging. Ultrasound is noninvasive, has an accuracy (sensitivity) rate of 96% in detecting gallstones, and is the least expensive imaging technique.
- Cholecystography (cholecystogram, gallbladder series, gallbladder x ray). This type of study shows how the gallbladder contracts after the patient has eaten a high–fat meal.
- Fluoroscopy. This imaging technique allows the doctor to distinguish between jaundice caused by pancreatic cancer and jaundice caused by gallbladder or bile duct disorders.
- Endoscopy (ERCP). ERCP uses a special dye to outline the pancreatic and common bile ducts and locate the position of the gallstones.
- Radioisotopic scan. This technique reveals blockage of the cystic duct.

Treatment

One-third of all patients with gallstones never experience a second attack. For this reason many doctors advise watchful waiting after the first episode. Reducing the amount of fat in the diet or following a sensible plan of gradual weight loss may be the only treatments required for occasional mild attacks. A patient diagnosed with gallstones may be able to manage more troublesome episodes by:

- applying heat to the affected area
- resting and taking occasional sips of water
- using non-prescription forms of acetaminophen (Tylenol or Anacin–3)

A doctor should be notified if pain intensifies or lasts for more than three hours; if the patient's fever rises above 101°F (38.3°C); or if the skin or whites of the eyes turn yellow.

Surgery

Surgical removal of the gallbladder (**cholecystectomy**) is the most common conventional treatment for recurrent attacks. Laparoscopic surgery, the technique most widely used, is a safe, effective procedure that involves less pain and a shorter recovery period than traditional open surgery. In this technique, the doctor makes a small cut (incision) in the patient's abdomen and removes the gallbladder through a long tube called a laparoscope.

Nonsurgical approaches

Patients who are too ill for surgery may benefit from gradual medical dissolution therapy with ursodeoxycholic acid (ursodiol). This technique typically requires months of therapy before stones are dissolved.

Alternatives

Alternative therapies, like non-surgical treatments, may provide temporary relief of gallstone symptoms. Alternative approaches to the symptoms of gallbladder disorders include homeopathy, Chinese traditional herbal medicine, and **acupuncture**. Dietary changes may also help relieve the symptoms of gallstones. Since gallstones seem to develop more often in people who are obese, eating a balanced diet, exercising, and losing weight may help keep gallstones from forming.

Prognosis

Forty percent of all patients with gallstones have "silent gallstones" that produce no symptoms. Silent stones, discovered only when their presence is indicated by tests performed to diagnose other symptoms, do not require treatment.

Gallstone problems that require treatment can be surgically corrected. Although most patients recover, some develop infections that must be treated with **antibiotics**.

In rare instances, severe inflammation can cause the gallbladder to burst. The resulting infection can be fatal.

Prevention

The best way to prevent gallstones is to minimize risk factors. Obese adults who lose large amounts of weight very quickly including those who undergo **bariatric surgery** are at high risk for the development of gallstones. Prophylactic treatment with ursodeoxycholic acid may be prescribed in these situations.

WWW.BOOKBAZ.IR

Participation in regular **exercise** may decrease the probability of gallstone formation in some people.

Gambling disorder

Definition

Gambling disorder (GD), sometimes also called pathological gambling disorder, occurs when a person gambles compulsively to such an extent that the wagering has a severe negative effect on his or her job or career, relationships, mental health, or other important aspects of life. The person may continue to gamble even after they have developed social, economic, interpersonal, or legal problems as a result of the gambling.

The related medical term "ludomania" is defined as a progressive urge to gamble, one that eventually becomes a gambling disorder characterized by frequent, uncontrollable episodes of compulsive gambling. Medical professionals can diagnosis clinical pathological gambling when the patient meets certain criteria. Such problem gambling is considered an impulse control disorder in medicine.

Demographics

About twice as many males as females in the United States are diagnosed with gambling disorder. Relatively few women, however, are in treatment programs for the disorder, probably because of the greater social stigma attached to women who gamble. As a rule, men diagnosed with gambling disorder began gambling as teenagers, whereas women tend to start compulsive gambling at a later age and develop a gambling problem faster than men. In addition, women are developing a gambling disorder at rates that are up to 25% higher than are men. Gambling disorder also tends to be more common in minority groups and in people of a lower socioeconomic status. About 25% of people diagnosed as pathological gamblers had a parent with the disorder. People who smoke tobacco or abuse alcohol are more likely to have GD than people who do not use these substances.

As much as 5% of the general population in the United States may meet criteria for gambling disorder at some point in their lives. In some countries, such as Australia, the number is thought to be as high as 7%.

Description

Gambling disorder is characterized by uncontrollable gambling well beyond the point of a social or recreational activity, such that the gambling has a major disruptive effect on the gambler's life. People who are pathological gamblers may lose their life savings and may even commit crimes (e.g., stealing, embezzling, or forging checks) to get money for their "habit." Relationships and jobs may also be lost as a result of the disorder.

Gambling disorder is sometimes considered as an example of a process, or behavioral, **addiction**, which is as distinct from an addiction to such substances as food, drugs, tobacco, or alcohol. In

process addictions, the characteristic "rush" or "high" comes from the series of steps or actions that are involved in the addictive behavior. With gambling, the "high" may be stimulated by the social atmosphere or group setting of the casino, race track, or bingo hall as well as by the excitement of risk-taking. Some gamblers have a "lucky" outfit, item of clothing, or accessory that they wear or take along when gambling; sometimes putting on the outfit or item in question is enough to start the "rush."

People with gambling disorder may engage in many different types of gambling activities. These may include games of chance that are found in casinos, such as slot machines, card games, and roulette. Many of these games are now available on the Internet, the chief difference being that the bettor uses a credit card instead of cash or chips. Other gambling activities may include the state lottery, horse or dog racing, or bingo. The person may place bets on the outcome of an election, baseball or football games, or even the weather on a particular day. Pathological gambling usually develops slowly; people tend to begin with acceptable levels of social or recreational gambling and slowly progress to pathological gambling. In most cases the disorder develops slowly over a period of years; however, there are cases of patients who gambled socially for decades and then began to gamble compulsively under the impact of a major life stressor, such as divorce or being laid off from work.

Causes and symptoms

Causes

Gambling disorder is considered a brain disease similar to other disorders of addiction, like alcohol or drug addiction. The primary mechanism underlying the development and persistence of pathological gambling is the brain's dopamine-based reward system, which is thought to underlie many disorders of addiction or impulse control. The central pathway involved is the mesolimbic pathway of dopamine signaling. This pathway exhibits alterations in dopamine levels or signaling in response to some substances; and a similar dopamine response is thought by medical professionals to underlie process addictions, including pathological gambling. The key feature in the brain involved in this process is the nucleus accumbens.

There also are significant psychological factors that may contribute to excessive gambling, often associated with the common comorbidities of pathological gambling, including depression and substance use disorder. People who are pathological gamblers may use gambling as an emotional escape from depression; this pattern appears more often in females with the disorder than in males. Some people who are pathological gamblers seek the mood alteration associated with gambling—specifically the excitement and energy that they find in the activity—more than the money involved. In other words, the person with the disorder is reinforced by an emotional "high" rather than by the money itself. Some researchers have found that males diagnosed with gambling disorder were more likely to have been diagnosed with **attention deficit hyperactivity disorder (ADHD)** as children than males in the general population. Other researchers have described compulsive gamblers in general as highly competitive people who are restless and easily bored. People with this disorder exhibit many features in common with those who have substance use disorder, including the urge to engage in the behavior, mounting tension before engaging in the behavior, relief or euphoria during the behavior, a return of the urge, and the presence of external cues that may trigger the behavior.

Other theories about the causes of gambling disorder emphasize cognitive distortions rather than mood problems. Pathological gambling has been associated with dysfunctional thinking patterns; many people with this disorder are highly superstitious or believe that they can control the outcome of events when they are gambling. Many people diagnosed with the disorder also have distorted beliefs about money, tending to see it at the same time as the source of all their problems and the answer to all their problems.

One social change that has been linked with the rise in the number of adults diagnosed with gambling disorder in the United States is the increased availability of legalized gambling. Some studies show that proximity to a casino is associated with increased rates of pathological gambling in a population. However, other studies show the opposite. For instance, a 2008 study in the journal *Psychology of Addictive Behaviors* found that the rates of pathological gambling were not higher near a casino when compared to rates away from such establishments. The study did find, however, that participation and monetary expenditures in gambling establishments were higher the closer in distance individuals were to gambling places.

WWW.BOOKBAZ.IR

Symptoms

The symptoms of pathological gambling include preoccupation with gambling activity, often to the extent of interfering with the person's occupational or social functioning. The person often cannot control the gambling behavior, continuing to place bets or go to casinos in spite of attempts to cut back or stop. One common behavior in persons with gambling disorder is "chasing," which refers to betting larger sums of money or taking greater risks in order to undo or make up for previous losses. The person may also lie about his or her gambling or engage in such antisocial behaviors as stealing, credit card fraud, check forgery, embezzling from an employer, or similar dishonest behaviors in order to obtain more money for gambling.

Diagnosis

Pathological gambling disorder is more likely to be diagnosed when the affected person's spouse or family becomes concerned than to be self-reported. Denial is common among persons with the disorder. The *Diagnostic and Statistical Manual of Mental Disorders* specifies that the patient must have at least five of the following symptoms to meet criteria for the disorder:

- thinks about gambling all the time
- uses larger and larger amounts of money when gambling
- has tried to stop gambling but failed
- is moody or cranky when trying to stop gambling
- uses gambling as a way to escape problems
- keeps gambling to try to make back money that had previously been lost ("chasing")
- lies about the extent of gambling
- has tried to make money for gambling by engaging in illegal or immoral behavior
- has problems at work or home caused by the gambling
- relies on other people to get him or her out of financial problems caused by the gambling.

Gambling disorder is distinguished from social gambling, in which the person is typically socializing with friends, gambling for a limited period of time, and gambling with a limited sum of money that they can afford to lose. GD is also distinguished from professional gambling, in which participants limit their risks, and discipline their behaviors. Lastly, gambling disorder must be distinguished from a manic episode; in most cases, the distinguishing feature of the disorder is that the manic-like behavior disappears after the person leaves the gambling setting, and that other symptoms of a manic episode, such as euphoria, irritability, and sleeplessness, are not present.

KEY TERMS

Dopamine—A chemical neurotransmitting compound found in the brain that is a precursor of epinephrine.

Functional magnetic resonance imaging—A special type of magnetic resonance imaging (MRI) scan that measures changes in blood flow and blood oxygenation within the body; often abbreviated fMRI.

Histrionic—Relating to being very dramatic or excessive in behavior.

Narcissistic—Relating to a personality disorder in which an individual overestimates his or her own abilities or appearance, such as an extraordinary ability to win at gambling.

Nucleus accumbens—Abbreviated NAcc and also known as accumbens nucleus, is a part of the brain reward system, located in the limbic system, that processes information related to motivation and reward.

Opioid antagonist—A type of receptor antagonist (drug) that acts on opioid receptors.

Pathological—Uncontrollable in nature; relating to disease.

Treatment

There are a number of different treatments for gambling disorder. Psychodynamic **psychotherapy** attempts to uncover any underlying psychological factors that trigger the gambling. For people who are gambling to escape, such as those who are depressed, this approach may be very successful. Treating any substance abuse problems that may coexist with the pathological gambling can also be helpful. Other types of treatments involve behavioral techniques used to teach relaxation and avoidance of stimuli associated with gambling. Aversion therapy appears to be successful in treating pathological gambling disorder in highly motivated patients with some insight into the problem, but is not helpful for patients who are less educated or resistant to behavioral methods of treatment.

Gamblers Anonymous (GA) is a twelve-step program modeled after Alcoholics Anonymous (AA).

The gambler's admission that she or he does have a gambling problem, and a willingness to go to meetings are considered the first steps in treating gambling disorder. Looking realistically at what gambling has done to a person's life and a willingness to work hard to stop gambling are also important parts of GA. People involved in this program are expected to attend meetings regularly, make amends for wrongs that their gambling has caused, and find a sponsor (usually of the same gender) to help them through the program. GA also expects people who stop gambling to understand that they probably will never be able to gamble again socially, just as recovering alcoholics cannot drink socially.

Pharmacological treatments for pathological gambling and other process addictions are still being developed and explored. In studies reported thus far, the most effective pharmaceutical treatment has been opioid antagonists, such as naltrexone (Depade, ReVia) or nalmefene (Revex), possibly because of their effects on opioid pathways that interact with dopamine signaling pathways in the brain reward system. Treatment may also target co-morbidities of pathological gambling, such as using **selective serotonin reuptake inhibitors** (SSRIs) if mood disorder or **obsessive-compulsive disorder** is present.

Doctors at the University of California at Los Angeles (UCLA), are treating gambling disorders as a brain disease. The amount and severity of gambling disorder in California is increasing annually. Consequently, the state provided $15 million for three years, beginning around 2011, to fund treatment programs for California citizens with a gambling disorder. Dr. Timothy Fong, the codirector of the UCLA Gambling Studies Program, works with the state's Office of Problem Gambling to design, develop, and evaluate treatment programs for gambling disorder. Part of the state funding for gambling disorder is to certify nearly 300 mental health therapists in the treatment of gambling problems.

Prognosis

There are very few statistics on the number of people successfully treated for gambling disorder. It is estimated that one-third of all people with gambling disorder can recover from the disease without treatment. However, that still leaves two-thirds who do not recover. In fact, as many as two out of three people who begin treatment (medication, therapy, or both) for gambling disorder drop out before its completion. Consequently, the negative effects of gambling disorder often leave their lives, and their family, in ruin. It is estimated that $5 billion is spent annually on gambling in the United States. However, during each of those years, people with a gambling disorder are estimated to have accrued tens to hundreds of thousands of dollars in debt.

Besides financial problems, people with gambling disorders suffer from a multitude of mental problems, such as an increased risk of causing domestic violence and **child abuse**. The mental problems are not reserved to the problem gamblers. Children of gamblers with problems are at increased risk from suffering behavioral problems, depression, and substance abuse.

Treatment for any underlying psychological disorders or substance abuse can be very helpful. Sometimes **family therapy** is recommended. Some types of relaxation or behavioral therapy can also be helpful. Gamblers Anonymous can help in many cases, although the program has a high dropout and recurrence rate, and there are few studies that fully analyze the benefits or efficacy of the program. For many people, a combination of more than one of these approaches may be most effective. Even when a person has successfully stopped compulsive gambling, it is unlikely that he or she will ever be able to gamble socially again, or even spend time in places where he or she once gambled.

The Institute for Research on Gambling Disorders announced that five research projects were awarded in 2010 for the study of gambling disorders. The grants, which totaled $380,466, were awarded by the National Center for Responsible Gaming to researchers at Duke University (North Carolina), Southern Illinois University, the University of Florida, the University of Minnesota, and the University of Missouri.

The research studies were in the grant areas called Exploration Grants, Seed Grants, and Large Grants. The Exploration Grants involve evaluating the risk difference of online gambling versus non-Internet based gambling. A virtual Internet site will be built to simulate online gambling. Subjects will be divided into a pathological gambling group and a control group. Using functional **magnetic resonance imaging** (fMRI) scans, the researchers from the University of Florida will research the neurological activity in the brain when excessive gambling is involved.

Duke University researchers were granted a Seed Grant to test the hypothesis that whether "someone makes a risky or safe choice depends not simply on preferences, but on the strategies they use to acquire and integrate new information." The study will provide further information on the reasons why some

WWW.BOOKBAZ.IR

people make risky decisions while gambling. Another Seed Grant was awarded to scientists at Southern Illinois University to use fMRI to examine the brain activity of "disordered gamblers" before and after undergoing acceptance and commitment therapy, which is a new therapy being developed to help treat gambling disorders.

Researchers at the University of Missouri were awarded a Large Grant of $172,500 to test whether college students report more or less gambling when they are provided information about their own behaviors while gambling (in what is called "personalized feedback-only intervention"). In addition, University of Minnesota scientists will study the various factors, such as race and gender, which distinguish recreational gamblers and pathological gamblers. They will also study factors that may be responsible for turning recreational gamblers into problem gamblers. This study will use data from the National Epidemiologic Survey on Alcohol and Related Conditions.

In addition, a research study performed in Australia has shown that nearly one in five problem gamblers (17%) has attempted **suicide**. Their statistics are based on patients entering the emergency department at the Alfred hospital in Prahran, Victoria, Australia. The report concluded that this rate of suicide among problem gamblers is about 20 times the rate in a normal population without gambling problems. Commenting on the results of the Australian report, state gaming minister Tony Robinson stated that "one of the underlying drivers of problem gambling is a pre-existing mental health condition."

Prevention

Prevention of pathological gambling disorder is very difficult because it is impossible to predict when someone will react to gambling in a way that leads to compulsive gambling. If, however, a person begins to feel that he or she may have a problem, immediate treatment can prevent the development of a disorder that affects all areas of life and may have legal as well as economic consequences. Given the role of proximity to available gambling in the development of the disorder, this factor may be a target in prevention.

Gamete intrafallopian transfer *see* **Infertility therapies**

Gamma globulin

KEY TERMS

Hepatitis—Inflammation of the liver caused by a virus, chemical or drugs. There are several different types of hepatitis, including the most common forms: hepatitis A, hepatitis B, and hepatitis C.

Immune system—The body's natural defenses against disease and infection.

Inflammation—Pain, redness, swelling, and heat that usually develop in response to injury or illness.

Definition

Gamma globulin is a type of protein found in the blood. When Gamma globulins are extracted from the blood of many people and combined, they can be used to prevent or treat infections.

Purpose

This medicine is used to treat or prevent diseases that occur when the body's own immune system is not effective against the disease. When disease-causing agents enter the body, they normally trigger the production of antibodies, proteins that circulate in the blood and help fight the disease. Gamma globulin contains some of these antibodies. When Gamma globulins are taken from the blood of people who have recovered from diseases such as **chickenpox** or hepatitis, they can be given to other people to make them temporarily immune to those diseases. With hepatitis, for example, this is done when someone who has not been vaccinated against hepatitis is exposed to the disease.

Some diseases or disorders that may require treatment with Gamma globulin include:

- skin diseases such as lupus erythematosus and scleroderma
- hematologic disorders such as idiopathic thrombocytopenia purpura (ITP)
- Kawasaki disease
- graft versus host disease associated with bone marrow, stem cell, and other transplant procedures

Description

Gamma globulin, also known as immunoglobulin, immune serum globulin or serum therapy, is injected either into a vein (the most common method) or into a muscle. When injected into a vein, it produces results more quickly than when injected into a muscle.

U.S. brand names

Some of the brand names of products that contain Gamma globulin and that are sold in the United States include:

- Gammagard S/D
- Gammar-IV
- Gamimmune-N
- Iveegam
- Polygam S/D
- Sandoglobulin
- Venoglobulin-I or Venoglobulin-S
- Carimune/Panglobulin
- Gamunex

Recommended dosage

Doses are different for different people and depend on the person's body weight and the condition for which he or she is being treated.

Precautions

Anyone who has had unusual reactions to Gamma globulin in the past should let his or her physician know before taking the drugs again. The physician should also be told about any **allergies** to foods, dyes, preservatives, or other substances.

Individuals who have a history of reactions to blood products or who have experienced a blood product **transfusion** reaction in the past should inform

WWW.BOOKBAZ.IR

their healthcare providers prior to receiving Gamma globulin products.

People who have certain medical conditions may have problems if they take Gamma globulins. For example:

- Gamma globulins may worsen heart problems or deficiencies of immunoglobin A (IgA, a type of antibody.)
- Certain patients with low levels of Gamma globulins in the blood (conditions called aGamma globulinemia and hypoGamma globulinemia) may be more likely to have side effects when they take Gamma globulin.
- Patients receiving Gamma globulin who have a history of liver and/or kidney problems should be monitored closely while receiving this product.

Side effects

Minor side effects such as **headache**, backache, joint or muscle **pain**, and a general feeling of illness usually go away as the body adjusts to this medicine. These problems do not need medical attention unless they continue.

Other side effects, such as breathing problems or a fast or pounding heartbeat, should be brought to a physician's attention immediately.

Anyone who shows the following signs of overdose should check with a physician immediately:

- unusual tiredness or weakness
- dizziness
- nausea
- vomiting
- fever
- chills
- tightness in the chest
- red face
- sweating

Interactions

Anyone who takes Gamma globulin should let the physician know all other medicines he or she is taking and should ask whether interactions with Gamma globulin could interfere with treatment.

Gamma-glutamyl transferase test *see* **Liver function tests**

Gamma Knife surgery

Definition

Gamma Knife surgery, also referred to as stereotactic radiosurgery, utilizes intersecting radiation beams targeted to a specific location in the brain to treat brain tumors and other abnormalities within the brain. Despite the name, no surgical incisions are required with this type of procedure.

Purpose

Gamma Knife radiosurgery is used to treat benign and malignant brain tumors which are considered to be inoperable because of their location in the brain which makes them inaccessible to conventional surgical approaches. This type of radiosurgery is also effective in treating cancer which has spread or metastasized to the brain.

Gamma Knife surgery can also be used to treat many conditions including the following:

- tumors of the pituitary gland which are located deep in brain tissue
- benign tumors such as schwannomas or acoustic neuromas which affect the acoustic nerve and can lead to problems with balance and hearing if left untreated
- trigeminal neuralgia, a condition which causes severe facial pain
- arteriovenous malformations (AVMs), a condition in which abnormal veins and arteries connect directly to each other rather than through the normal anatomic network of smaller blood vessels known as capillaries

Gamma Knife surgery is also increasingly used to treat patients with tumors in areas other than the brain. Recent studies report the effectiveness of this technology on the treatment of inoperable lung

tumors and in the treatment of cancers of the head and neck.

Demographics

According to the manufacturer, the number of patients treated with Gamma Knife surgery has increased by more than 300% over the past five years and more than 500,000 people have received treatment utilizing this technology to date. There are over 125 Gamma Knife treatment centers in the United States.

Description

Gamma Knife technology was developed in the 1950s by Dr. Lars Leksell, a Swedish professor of **neurosurgery**, and radiation biologist, Borje Larsson, who pioneered the use of radiation beams in combination with stereotactic or precise guiding devices that could focus the beams with surgical precision. Thus, the term stereotactic (guided) radio(radiation) surgery was coined. In 1967, the first Gamma Knife device, which used cobalt-60 as the radiation source, was constructed. Gamma Knife technology became available in the United States in 1987.

Current Gamma Knife technology utilizes cobalt-60 photon radiation to deliver the radiation dose to targeted areas within the brain with pinpoint accuracy while sparing adjacent normal tissue from the deleterious effects of radiation. The radiation dose is calculated specifically for each patient taking into account tumor type, tumor shape, and tumor location including tumor depth. The precise dose to be delivered is determined based on the results of highly sophisticated imaging tests such as angiograms, **magnetic resonance imaging** (MRI), and/or computed tomography (CT) scans. Currently, most neurosurgeons use one MRI scan to determine the area to be treated. The results of these imaging tests are then placed into dose planning software which can model the affected area in 3 dimensions. The specific dose, individualized for each patient, is based on the results obtained from the treatment planning software, and is calculated by a radiation oncologist and a medical physicist.

Despite being called surgery, no actual surgery and no blade or knife is involved in the treatment process. There is no incision made in Gamma Knife surgery and no brain tissue is removed from the body. Radiation, delivered by a machine, is targeted into the affected brain tissue while sparing adjacent normal tissue.

Each Gamma Knife treatment unit can store 200 sources of cobalt-60 radiation. Thousands of radiation beams can then be generated from these sources and targeted to the area of the brain to be treated. Each individual beam does not contain enough energy to harm normal tissue as it passes through brain tissue to reach the target. However, when all of the beams intersect and converge on the target, the combined effect of the energy in all of the radiation beams is powerful enough to treat the tissue in the area. According to the manufacturer, by keeping the patient immobilized during the actual treatment in combination with using three-dimensional treatment planning that is computer-aided, the radiation dose can be targeted with such precision that the level of accuracy is about one-tenth of one millimeter, which is about the thickness of an individual strand of human hair. The end result is that the calculated radiation dose reaches the targeted tissue, adjacent normal tissue is spared and the entire process is accomplished in a single treatment session.

Preparation

Unlike other **radiation therapy** procedures which may require multiple daily treatment visits, treatment using Gamma Knife technology is typically completed in one visit to the treatment center and is done on an outpatient basis. The patient will be asked not to consume food or water past midnight the night before the procedure is scheduled. Patients should ask their physicians if they may consume a small amount of water with their medications, however. Patients should inform the physician if they are taking oral medications or insulin to control diabetes.

Patients will also be asked if they are allergic to shellfish or iodine in anticipation of radiologic imaging techniques they will undergo as part of the treatment planning process. Patients should inform the staff if they have any implanted medical devices such as **pacemakers**, cardiac stents, artificial heart valves and other similar devices.

The staff at most treatment facilities will instruct the patient not to wear jewelry or makeup, including nail polish, on the day of the procedure. Once the treatment planning process begins the patient will be asked to remove eyeglasses, **contact lenses**, dentures, and wigs.

Preparation for treatment involves application of a stereotactic head frame. The frame, which is comprised of lightweight aluminum material, is attached to the head using four screws after local **anesthesia** is applied to the sites where the screws will be inserted. The primary purpose of the head frame is to allow for the precise targeting of the area within the brain which is to be treated. Hair will not be cut or shaved to

WWW.BOOKBAZ.IR

KEY TERMS

Benign—Not cancerous.

Malignant—Cancerous.

Radiosurgery—Precise delivery of a large dose of radiation to a targeted area within the brain.

Stereotactic—Precise guidance or positioning.

position the head frame. The frame is designed to limit movement during radiologic imaging procedures such as magnetic resonance imaging (MRI) and/or computed tomography (CT) scanning and during the actual treatment process. An angiogram may also be required depending on the particular condition being treated. During the imaging process, a device called a coordinate box is affixed to the head frame. The coordinate box provides reference points on the images to facilitate development of a treatment plan. The time needed to secure the head frame and to complete the imaging tests, which are part of the treatment planning process, typically takes several hours. Results of the imaging tests are directed to a computerized planning system. The patient is allowed to rest while the treatment plan is being individualized and customized for that specific patient, however the head frame must remain attached during this time.

Once treatment planning is complete, the actual treatment begins. The patient remains awake during treatment and may be able to listen to music during the procedure. The actual treatment may take a few minutes or more than an hour depending on the size, location, and configuration of the area in the brain being targeted for treatment. The patient can communicate with the staff during the treatment if necessary and will be monitored at all times with audio and video monitoring.

While wearing the head frame which is then attached to a helmet located inside the treatment machine, the patient is positioned on a movable treatment table. The treatment table moves into a section of the treatment machine that is shaped like a dome. The patient may not know unless told that the treatment has started because the treatment itself is silent and does not cause **pain** nor is the patient able to feel any radiation.

Aftercare

Once the treatment is completed, the head frame is removed and the patient may be allowed to go home. Patients who have undergone **angiography** may have to lie still and remain at the treatment center for several hours to ensure that bleeding from the angiogram catheter entry and exit site does not occur and that swelling at the site is minimized. Rarely, some patients may have to be monitored overnight.

Some individuals may experience minor **headache** and pain at the site on the scalp where the head frame was affixed. Some patients may also experience minor swelling at the site. The effects from the actual radiation treatment are not immediate and may not be felt for weeks, months, or longer after the treatment. Most individuals can return to their regular routine in one to two days after treatment.

After the procedure, some patients may experience swelling in brain tissue adjacent to the area being treated. The swelling can usually be controlled with oral **steroids**.

Follow-up care usually involves additional images of the area which can be obtained by angiography, MRI, and/or CT scans. The results of these imaging studies are compared to the studies done before the procedure to determine whether the stereotactic radiosurgery procedure was effective.

Risks

Due to the noninvasive nature of this procedure, there are minimal risks involved with Gamma Knife surgery. Some patients, especially pediatric patients, may require **sedation** and/or anesthesia to complete the treatment planning process and the actual treatment. Rarely, a small number of these patients may experience side-effects and risks associated with sedation and/or anesthesia.

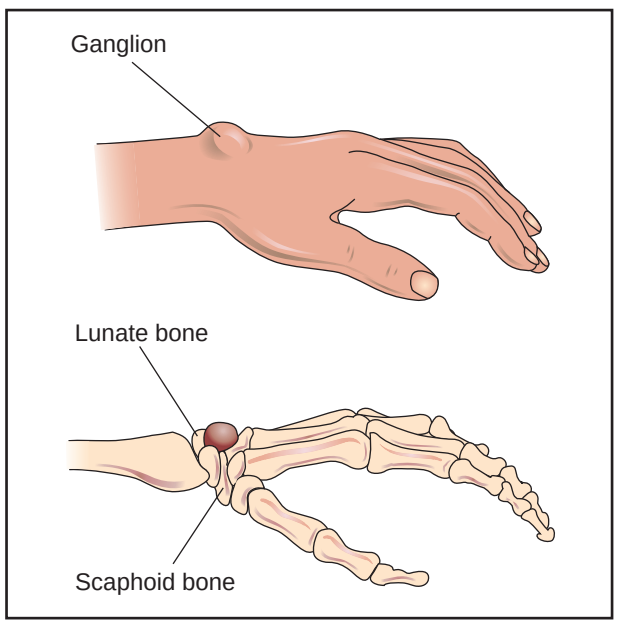
Ganglion

Definition

A ganglion is a small, usually hard sac-like swelling or cyst (basically a bump or mass) above a tendon or in the capsule that encloses a joint. As described by the American Academy of Orthopaedic Surgeons, ganglion "rise out of a joint, like a balloon on a stalk." Also called synovial hernias or synovial cysts, ganglions are noncancerous. Although they are generally harmless, these cysts can sometimes cause **pain**, interfere with function of the affected body part, or give the affected person an unsightly appearance at its locality. Ganglions can appear anywhere on the body, but most often they appear on the top of the wrist, the palm (under) side of the wrists, the base of the finger on the palm side, and the top of the end joint of the finger.



A ganglion is a non-cancerous cyst filled with a thick, jelly-like fluid. Ganglions can develop on or beneath the surface of the skin, most likely on the hand or wrist, although runners and skiers often develop them on the foot. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Description

A ganglion is a noncancerous cyst filled with a clear, thick, jelly-like fluid. Ganglion cysts are usually round or oval. They develop from the tissue (called synovium) that lines a joint or tendon, and they can develop on or beneath the surface of the skin. The synovium, which can be from joint linings, ligaments, and tendon sheaths, produces thin fluid to lubricate the joint and/or tendon. However, sometimes a cyst forms from the synovium when the tissue fills with a thickened clear or translucent fluid with a texture similar to jelly. Ganglions may vary from the size of a pea to about 1 in (2.5 cm) in diameter. They usually occur on people between the ages of 15 and 40 years and more frequently in women.

Ganglion cysts usually develop in several of the joints in the hand and wrist. In the hand, they often develop on the end joint of the finger and at the base of the finger. On the wrist, they develop both on the top and on the underside of the wrist. Most ganglion develop on the hands (especially the wrists) and on the foot (especially the ankles).

Demographics

This condition is common in people who bowl or who play handball, racquetball, squash, or tennis. Runners and athletes who jump, ski, or play contact sports often develop foot ganglions. Women gymnasts frequently are afflicted with ganglion cysts. Although most ganglions form from unknown reasons, they can develop as a result of injury (**trauma**) to the tendon or joint or can be an early symptom of arthritis. Ganglion cysts that develop at the end joint of the finger (what are called mucous cysts) are usually found on women between the ages of 40 and 70 years.

Causes and symptoms

Mild sprains or other repeated injuries can irritate and tear the thin membrane covering a tendon, causing fluid to leak into a sac that swells and forms a ganglion. Although injuries can cause ganglions to form, in most cases the medical community does not understand why they develop. People are at increased risk for ganglions if they are young-to-middle age and

WWW.BOOKBAZ.IR

active, if they are female, have **osteoarthritis**, or have had joint or tendon injuries.

Ganglions are usually painless, but range of joint motion may be impaired. Some ganglion can be painful if they press onto a neighboring nerve—even small ones that are not noticeable on the skin. When the nerve is adversely affected, tingling, muscle weakness, or numbness can also be present. Flexing or bending the affected area can cause discomfort, as can continuing to perform the activity that caused the condition.

Cysts on the surface of the skin usually develop slowly but may result from injury or severe strain. An internal ganglion can cause soreness or a dull, aching sensation, but the mass cannot always be felt. Most ganglions are barely visible, appearing as minor swellings on the affected area but usually without the appearance of inflammation. Certain noticeable cysts appear on the back of the knee. Such a cyst is called a Baker cyst, named after the British surgeon William M. Baker (1839–1896) who first described it. Also called a popliteal cyst, this type on the knee or other body part may feel tight. Symptoms sometimes become evident only when the cyst causes pressure on a nerve or outgrows the membrane surrounding it.

Diagnosis

Diagnosis is usually made through **physical examination** as well as such imaging studies as x ray, **ultrasound**, and **magnetic resonance imaging** (MRI). X-ray scans show a distinct image of dense structures such as bone. Although x rays cannot find ganglions, they can help identify such conditions as arthritis and bone tumors. MRI scans show soft tissues such as ganglion cysts. Once a cyst is diagnosed, fluid can be drawn from the cyst and evaluated. The doctor may also shine a light to determine if the cyst is a solid mass or filled with fluid.

Treatment

Some ganglions disappear without treatment, and some reappear despite treatment. Individuals with ganglions sometimes take **acetaminophen** (Tylenol), ibuprofen (Advil, Motrin IB), naproxen (Aleve) or other over-the-counter pain relievers. These can be used to control mild pain. **Steroids** or local anesthetics may be injected into cysts that cause severe pain or other troublesome symptoms. A brace or splint may be worn to immobilize the area, such as on the wrist. Limited mobility of the affected area helps prevent the cyst from becoming larger and oftentimes more painful.

KEY TERMS

Cortisone—A 21-carbon steroid hormone.

Magnetic resonance imaging (MRI)—A medical test that uses a magnetic field and pulses of radiowave energy to produce images of organs and structures located in the interior of the human body.

Osteoarthritis—A type of arthritis that occurs when the protective cartilage on the ends of bones wears down.

Ultrasound—A diagnostic imaging technique used for visualizing subcutaneous body structures, including internal organs, joints, muscles, and tendons for possible pathology or lesions.

Sometimes, the ganglion fluid is removed with aspiration; that is, the fluid is drawn out with a needle and syringe. Aspiration is often used for the removal of ganglions located on the top of the wrist. Along with the aspiration procedure, an injection of cortisone may be used to reduce inflammation, pain, and swelling. A persistent or recurrent ganglion should be evaluated by a doctor for signs of arthritis such as **rheumatoid arthritis**.

Surgery performed in a hospital operating room or an outpatient facility is the only treatment guaranteed to remove a ganglion. However, the procedure does not prevent ganglions from returning. In surgical excision the entire ganglion, along with the stalk that attaches it to the joint or tendon, is resected (cut out). The condition can recur if the entire cyst is not removed. After surgery, patients may bathe or shower as usual but should keep the surgical site dry and covered with a bandage for two or three days after the operation. Patients may resume normal activities as soon as they feel comfortable doing so.

A doctor should be notified if the surgical site drains, bleeds, is painful, or becomes hot and swollen.

A medical physician should also be contacted if the post-surgical patient feels ill or develops a **headache** or muscle ache, becomes dizzy, or develops a **fever**.

Alternatives

Alternative treatment for ganglions historically involved hitting the cyst with a heavy object in order to burst it open. Long ago, ganglion cysts were commonly called Bible bumps because doctors would

often treat them by slamming a heavy book, usually a Bible, onto the cyst. However, this type of treatment is not a recommended in the twenty-first century because the force of the impact can damage the parts of the body surrounding the cyst. In addition, medical professionals do not recommend that unqualified persons try to puncture the cyst. Puncturing the cyst by a needle, for instance, is usually ineffective when done in such a manner and can lead to infection.

Prognosis

Possible complications include excessive postoperative bleeding and infection of the surgical site. Calcification, or hardening, of the ganglion is rare. Surgery of ganglion cysts is highly successful, but cysts may recur.

Prevention

Exercises that increase muscle strength and flexibility can prevent ganglions. Warming and cooling down before and after workouts may also decrease the rate of developing ganglions. Eliminating the activity that is straining the affected joint is a good way to reduce the likelihood of ganglion. For cysts that occur on the foot or ankle, improperly fitting footwear may be the problem. Once well-fitting shoes are worn, the ganglion usually will go away by itself.

REVISED BY WILLIAM A. ATKINS, BB, BS, MBA

Gangrene

Definition

Gangrene is the term used to describe the decay or death of an organ or tissue caused by a lack of blood supply. It is a complication resulting from infectious or inflammatory processes, injury, or degenerative changes associated with chronic diseases, such as **diabetes mellitus**.

Description

Gangrene may be caused by a variety of chronic diseases and post-traumatic, post-surgical, and spontaneous causes. There are three major types of gangrene: dry, moist, and gas (a type of moist gangrene).

Dry gangrene is a condition that results when one or more arteries become obstructed. In this type of gangrene, the tissue slowly dies, due to receiving little

A close-up of gangrene in the toes of a diabetic patient. *(Photo Researchers, Inc.)*

WWW.BOOKBAZ.IR

or no blood supply, but does not become infected. The affected area becomes cold and black, begins to dry out and wither, and eventually drops off over a period of weeks or months. Dry gangrene is most common in persons with advanced blockages of the arteries (arteriosclerosis) resulting from diabetes.

Moist gangrene may occur in the toes, feet, or legs after a crushing injury or as a result of some other factor that causes blood flow to the area to stop suddenly. When blood flow ceases, bacteria begin to invade the muscle and thrive, multiplying quickly without interference from the body's immune system.

Gas gangrene, also called myonecrosis, is a type of moist gangrene that is commonly caused by bacterial infection by *Clostridium welchii, C. perfringes, C. septicum, C. novyi, C. histolyticum, C. sporogenes*, or other species that are capable of thriving under conditions where there is little oxygen (anaerobic conditions). Once present in tissue, these bacteria produce gasses and toxins as they grow. Normally inhabiting the gastrointestinal, respiratory, and female genital tract, they often infect thigh **amputationwounds**, especially in those individuals who have lost control of their bowel functions (incontinence). Gangrene, incontinence, and debility often occur together in patients with diabetes, and it is in the amputation stump of diabetic patients that gas gangrene is often found to occur.

Other causative organisms for moist gangrene include various bacterial strains, including those of the *Streptococcus* and *Staphylococcus* genera. A serious, but rare form of infection with Group A *Streptococcus* can impede blood flow and, if untreated, can progress to synergistic gangrene, more commonly called necrotizing fasciitis, or infection of the skin and tissues directly beneath the skin.

Chronic diseases, such as diabetes mellitus, arteriosclerosis, or diseases affecting the blood vessels, such as Buerger's disease or Raynaud's disease, can cause gangrene. Post-traumatic causes of gangrene include compound **fractures**, **burns**, and injections given under the skin or in a muscle. Gangrene may occur following surgery, particularly in individuals with diabetes mellitus or other long-term (chronic) disease. In addition, gas gangrene can be also be a complication of dry gangrene or occur spontaneously in association with an underlying cancer.

In the United States, approximately 50% of moist gangrene cases are the result of a severe traumatic injury, and 40% occur following surgery. Car and industrial accidents, crush injuries, and gunshot wounds are the most common traumatic causes. Because of prompt surgical management of wounds with the removal of dead tissue, the incidence of gangrene from **trauma** has significantly diminished. Surgeries involving the bile ducts or intestine are the most frequent procedures causing gangrene. Approximately two-thirds of cases affect the extremities, and the remaining one-third involve the abdominal wall.

Causes and symptoms

Areas of either dry or moist gangrene are initially characterized by a red line on the skin that marks the border of the affected tissues. As tissues begin to die, dry gangrene may cause some **pain** in the early stages or may go unnoticed, especially in the elderly or in those individuals with diminished sensation to the affected area. Initially, the area becomes cold, numb, and pale before later changing in color to brown, then black. This dead tissue will gradually separate from the healthy tissue and fall off.

Moist gangrene and gas gangrene are distinctly different. Gas gangrene usually involves muscle, rather than skin. In moist or gas gangrene, there is a sensation of heaviness in the affected region that is followed by severe pain. The pain is caused by swelling resulting from fluid or gas accumulation in the tissues. This pain peaks, on average, between one to four days following the injury, with a range of eight hours to several weeks. The swollen skin may initially be blistered, red, and warm to the touch before progressing to a bronze, brown, or black color. In approximately 80% of cases, the affected and surrounding tissues may produce crackling sounds (crepitus), as a result of gas bubbles accumulating under the skin. The gas may be felt beneath the skin (palpable). In wet gangrene, the pus is foul-smelling, while in gas gangrene, there is no true pus, just an almost "sweet" smelling watery discharge.

Fever, rapid heart rate, rapid breathing, altered mental state, loss of appetite, **diarrhea**, **vomiting**, and vascular collapse may also occur if bacterial toxins are allowed to spread in the bloodstream. Gas gangrene can be a life-threatening condition and should receive prompt medical attention

Diagnosis

A diagnosis of gangrene will be based on a combination of patient history, a **physical examination**, and results of blood and other laboratory tests. A physician will look for a history of recent trauma, surgery, cancer, or chronic disease. Blood tests will be used to determine whether infection is present and determine the extent to which an infection has spread.

A sample of drainage from a wound, or obtained through surgical exploration, may be cultured with oxygen (aerobic) and without oxygen (anaerobic) to identify the microorganism causing the infection and to aid in determining which antibiotic will be most effective. The sample obtained from a person with gangrene will contain few, if any, white blood cells and, when stained (with Gram stain) and examined under the microscope, will show the presence of purple (Gram positive), rod-shaped bacteria.

X-ray studies and more sophisticated imaging techniques, such as **computed tomography scans** (CT) or **magnetic resonance imaging** (MRI), may be helpful in making a diagnosis since gas accumulation and muscle death (myonecrosis) may be visible. These techniques, however, are not sufficient alone to provide an accurate diagnosis of gangrene.

Precise diagnosis of gas gangrene often requires surgical exploration of the wound. During such a procedure, exposed muscle may appear pale, beefy-red, or in the most advanced stages, black. If infected, the muscle will fail to contract with stimulation, and the cut surface will not bleed.

Treatment

Gas gangrene is a medical emergency because of the threat that infection will spread rapidly via the bloodstream and infect vital organs. It requires immediate surgery and administration of **antibiotics**.

Areas of dry gangrene that remain free from infection (aseptic) in the extremities are most often left to wither and fall off. Treatments applied to the wound externally (topically) are generally not effective without adequate blood supply to support wound healing. Assessment by a vascular surgeon, along with x rays to determine blood supply and circulation to the affected area, can help determine whether surgical intervention would be beneficial.

Once the causative organism has been identified, moist gangrene requires the prompt initiation of intravenous, intramuscular, and/or topical broad–spectrum antibiotic therapy. In addition, the infected tissue must be removed surgically (**debridement**), and amputation of the affected extremity may be necessary. Pain medications (**analgesics**) are prescribed to control discomfort. Intravenous fluids and, occasionally, blood transfusions are indicated to counteract **shock** and replenish red blood cells and electrolytes. Adequate hydration and **nutrition** are vital to wound healing.

Although still controversial, some cases of gangrene are treated by administering oxygen under pressure greater than that of the atmosphere (hyperbaric) to the patient in a specially designed chamber. The theory behind using hyperbaric oxygen is that more oxygen will dissolve in the patient's bloodstream, and therefore, more oxygen will be delivered to the gangrenous areas. By providing optimal oxygenation, the body's ability to fight off bacterial infection are believed to be improved, and there is a direct toxic effect on bacteria that thrive in an oxygen-free environment. Some studies have shown that the use of hyperbaric oxygen produces marked pain relief, reduces the number of amputations required, and reduces the extent of surgical debridement required. Patients receiving hyperbaric oxygen treatments must be monitored closely for evidence of oxygen toxicity. Symptoms of this toxicity include slow heart rate, profuse sweating, ringing in the ears, **shortness of**

KEY TERMS

Aerobic—Organism that grows and thrives only in environments containing oxygen.

Anaerobic—Organism that grows and thrives in an oxygen–free environment.

Arteriosclerosis—Build-up of fatty plaques in arteries that can lead to the obstruction of blood flow.

Aseptic—Without contamination by bacteria or other microorganisms.

Crepitus—A crackling sound.

Gram stain—A staining procedure used to visualize and classify bacteria. The Gram stain procedure allows the identification of purple (Gram positive) organisms and red (Gram negative) organisms.

Hyperbaric oxygen—Medical treatment in which oxygen is administered in specially designed chambers, under pressures greater than that of the atmosphere, in order to treat specific medical conditions.

Incontinence—A condition characterized by the inability to control urination or bowel functions.

Myonecrosis—The destruction or death of muscle tissue.

Sepsis—The spreading of an infection in the bloodstream.

Thrombosis—The formation of a blood clot in a vein or artery that may obstruct local blood flow or may dislodge, travel downstream, and obstruct blood flow at a remote location.

WWW.BOOKBAZ.IR

breath, **nausea and vomiting**, twitching of the lips/cheeks/eyelids/nose, and convulsions.

The emotional needs of the patient must also be met. The individual with gangrene should be offered moral support, along with an opportunity to share questions and concerns about changes in **body image**. In addition, particularly in cases where amputation was required, physical, vocational, and **rehabilitation** therapy will also be required.

Prognosis

Except in cases where the infection has been allowed to spread through the bloodstream, prognosis is generally favorable. Anaerobic wound infection can progress quickly from initial injury to gas gangrene within one to two days, and the spread of the infection in the bloodstream is associated with a 20–25% mortality rate. If recognized and treated early, however, approximately 80% of those with gas gangrene survive, and only 15–20% require any form of amputation. Unfortunately, the individual with dry gangrene often has multiple other health problems that complicate recovery, and it is usually those other system failures that can prove fatal.

Prevention

Patients with diabetes or severe arteriosclerosis should take particular care of their hands and feet because of the risk of infection associated with even a minor injury. Education about proper **foot care** is vital. Diminished blood flow as a result of narrowed vessels will not lessen the body's defenses against invading bacteria. Measures taken towards the reestablishment of circulation are recommended whenever possible. Any abrasion, break in the skin, or infected tissue should be cared for immediately. Any dying or infected skin must be removed promptly to prevent the spread of bacteria.

Penetrating abdominal wounds should be surgically explored and drained, any tears in the intestinal walls closed, and antibiotic treatment begun early. Patients undergoing elective intestinal surgery should receive preventive antibiotic therapy. Use of antibiotics prior to and directly following surgery has been shown to significantly reduce the rate of infection from 20–30% to four to eight percent.

Gas embolism

Definition

Gas **embolism**, also called air embolism, is the presence of gas bubbles in the bloodstream that obstruct circulation.

Description

Gas embolism may occur with decompression from increased pressure; it typically occurs in ascending divers who have been breathing compressed air. If a diver does not fully exhale upon ascent, the air in the lungs expands as the pressure decreases, overinflating the lungs and forcing bubbles of gas (emboli) into the bloodstream. When gas emboli reach the arteries to the brain, the blood blockage causes unconsciousness. Gas embolism is second only to **drowning** as a cause of death among divers.

Gas embolism may also result from **trauma** or medical procedures such as catheterization and open heart surgery that allow air into the circulatory system.

Causes and symptoms

Gas embolism occurs independent of diving depth; it may occur in as little as 6 ft of water. It is frequently caused by a diver holding his breath during ascent. It may also result from an airway obstruction or other condition that prevents a diver from fully exhaling.

KEY TERMS

Compressed air—Air that is held under pressure in a tank to be breathed underwater by divers. A tank of compressed air is part of a diver's scuba (self-contained underwater breathing apparatus) gear.

Compression—An increase in pressure from the surrounding water that occurs with increasing diving depth.

Decompression—A decrease in pressure from the surrounding water that occurs with decreasing diving depth.

Emboli—Plural of embolus. An embolus is something that blocks the blood flow in a blood vessel. It may be a gas bubble, a blood clot, a fat globule, a mass of bacteria, or other foreign body. It usually forms somewhere else and travels through the circulatory system until it gets stuck.

Hyperbaric chamber—A sealed compartment in which patients are exposed to controlled pressures up to three times normal atmospheric pressure. Hyperbaric treatment may be used to regulate blood gases, reduce gas emboli, and provide higher levels of oxygen more quickly in cases of severe gas poisoning.

Recompression—Restoring the elevated pressure of the diving environment to treat gas embolism by decreasing bubble size.

The primary sign of gas embolism is immediate loss of consciousness; it may or may not be accompanied by convulsions.

Diagnosis

Any unconscious diver should be assumed to be the victim of gas embolism, regardless of whether consciousness was lost during or promptly after ascent. A doctor may also find pockets of air in the chest around the lungs and sometimes a collapsed lung from overinflation and rupture. Coughing up blood or a bloody froth around the mouth are visible signs of lung injury.

Treatment

Prompt **recompression treatment** in a hyperbaric (high-pressure) chamber is necessary to deflate the gas bubbles in the bloodstream, dissolve the gases into the blood, and restore adequate oxygenated blood flow to the brain and other organs. Recompression by returning the diver to deeper water will not work, and should not be attempted. The patient should be kept lying down and given oxygen while being transported for recompression treatment.

Before the diver receives recompression treatment, other lifesaving efforts may be necessary. If the diver isn't breathing, artificial respiration (also called mouth-to-mouth resuscitation or rescue breathing) should be administered. In the absence of a pulse, **cardiopulmonary resuscitation** (CPR) must be performed.

Prognosis

The prognosis is dependent upon the promptness of recompression treatment and the extent of the damage caused by oxygen deprivation.

Prevention

All divers should receive adequate training in the use of compressed air and a complete evaluation of fitness for diving. People with a medical history of lung cysts or spontaneous collapsed lung (pneumothorax), and those with active **asthma** or other lung disease must not dive, for they would be at extreme risk for gas embolism. Patients with conditions such as **alcoholism** and drug abuse are also discouraged from diving. Individuals with certain other medical conditions such as diabetes may be able to dive safely with careful training and supervision.

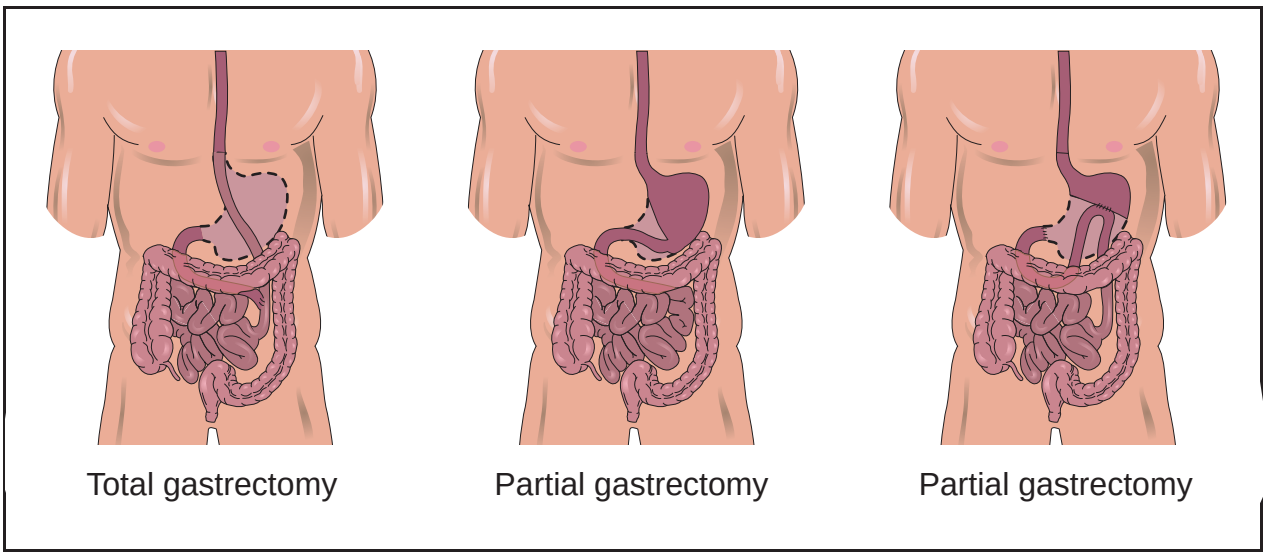
Gas gangrene *see* **Gangrene**

Gastrectomy

Definition

Gastrectomy is the surgical removal of all or part of the stomach.

WWW.BOOKBAZ.IR



Gastrectomy, the surgical removal of all or part of the stomach, is performed primarily to remove a malignant tumor or to cure a bleeding stomach ulcer. Following the gastrectomy, the surgeon may reconstruct the altered portions of the digestive tract so that it continues to function. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Purpose

Gastrectomy is performed for several reasons, most commonly to remove a malignant tumor or to cure a perforated or bleeding stomach ulcer.

Description

Gastrectomy for cancer

Removal of the tumor, often with removal of surrounding lymph nodes, is the only curative treatment for various forms of gastric (stomach) cancer. For many patients, this entails removing not just the tumor but part of the stomach as well. The extent to which lymph nodes should also be removed is a subject of some debate, but some studies show additional survival benefit associated with removal of a greater number of lymph nodes.

Gastrectomy, either total or subtotal (also called partial), is the treatment of choice for gastric adenocarcinomas, primary gastric lymphomas (originating in the stomach), and the rare leiomyosarcomas (also called gastric **sarcomas**). Adenocarcinomas are by far the most common form of **stomach cancer** and are less curable than the relatively uncommon lymphomas, for which gastrectomy offers good odds for survival.

After gastrectomy, the surgeon may "reconstruct" the altered portions of the digestive tract so that it continues to function. Several different surgical techniques are used, but, generally speaking, the surgeon attaches any remaining portion of the stomach to the small intestine.

Gastrectomy for gastric cancer is almost always done by the traditional "open" surgery technique, which requires a wide incision to open the abdomen. However, some surgeons use a laparoscopic technique that requires only a small incision. The laparoscope is connected to a tiny video camera that projects a picture of the abdominal contents onto a monitor for the surgeon's viewing. The stomach is operated on through this incision.

The potential benefits of laparoscopic surgery include less postoperative **pain**, decreased hospitalization, and earlier return to normal activities. The use of laparoscopic gastrectomy is limited, however. Only patients with early stage gastric cancers or those whose surgery is only intended for palliation—pain and symptomatic relief rather than cure—should be considered for this minimally invasive technique. It can only be performed by surgeons experienced in this type of surgery.

Gastrectomy for ulcers

Gastrectomy is also occasionally used in the treatment of severe peptic ulcer disease or its complications. While the vast majority of peptic **ulcers** (gastric ulcers in the stomach or duodenal ulcers in the duodenum) are managed with medication, partial gastrectomy is sometimes required for peptic ulcer patients who have complications. These include patients who do not respond satisfactorily to medical therapy, those who develop a bleeding or perforated

ulcer, and those who develop pyloric obstruction, a blockage to the exit from the stomach.

The surgical procedure for severe ulcer disease is also called an antrectomy, a limited form of gastrectomy in which the antrum, a portion of the stomach, is removed. For duodenal ulcers, antrectomy may be combined with other surgical procedures that are aimed at reducing the secretion of gastric acid, which is associated with ulcer formation. This additional surgery is commonly a **vagotomy**, surgery on the vagus nerve that disables the acid-producing portion of the stomach.

Preparation

Before undergoing gastrectomy, patients may need a variety of tests, such as x rays, **computed tomography scans** (CT scans), ultrasonography, or endoscopic biopsies (microscopic examination of tissue), to assure the diagnosis and localize the tumor or ulcer. **Laparoscopy** may be done to diagnose a malignancy or to determine the extent of a tumor that is already diagnosed. When a tumor is strongly suspected, laparoscopy is often performed immediately before the surgery to remove the tumor; this avoids the need to anesthetize the patient twice and sometimes avoids the need for surgery altogether if the tumor found on laparoscopy is deemed inoperable.

Aftercare

It is important to follow any instructions that have been given for postoperative care. Major surgery usually requires a recuperation time of several weeks.

Results

Overall survival after gastrectomy for gastric cancer varies greatly by the stage of disease at the time of surgery. For early gastric cancer, the five-year survival rate is up to 80–90%; for late-stage disease, the prognosis is bad. For gastric adenocarcinomas that are amenable to gastrectomy, the five-year survival rate is 10–30%, depending on the location of the tumor. The prognosis for patients with gastric lymphoma is better, with five-year survival rates reported at 40–60%.

Most studies have shown that patients can have an acceptable quality of life after gastrectomy for a potentially curable gastric cancer. Many patients will maintain a healthy appetite and eat a normal diet. Others may lose weight and not enjoy meals as much. Some studies show that patients who have total gastrectomies have more disease-related or treatment-related symptoms after surgery and poorer physical function than patients who have subtotal gastrectomies. There does not appear to be much difference, however, in emotional status or social activity level between patients who have undergone total versus subtotal gastrectomies.

Risks

Surgery for peptic ulcer is effective, but it may result in a variety of postoperative complications. After gastrectomy, as many as 30% of patients have significant symptoms. An operation called highly selective vagotomy is now preferred for ulcer management, and is safer than gastrectomy.

After a gastrectomy, several abnormalities may develop that produce symptoms related to food intake. This happens largely because the stomach, which serves as a food reservoir, has been reduced in its capacity by the surgery. Other surgical procedures that often accompany gastrectomy for ulcer disease can also contribute to later symptoms: vagotomy, which lessens acid production and slows stomach emptying, and **pyloroplasty**, which enlarges the opening between the stomach and small intestine to facilitate emptying of the stomach.

Some patients experience light-headedness, heart **palpitations** or racing heart, sweating, and **nausea and vomiting** after a meal. These may be symptoms of "dumping syndrome," as food is rapidly "dumped" into the small intestine from the stomach. This is treated by adjusting the diet and pattern of eating, for example, eating smaller, more frequent meals, and limiting liquids.

Patients who have abdominal bloating and pain after eating, frequently followed by nausea **andvomiting**, may have what is called the afferent loop syndrome. This is treated by surgical correction. Patients who have early satiety (feeling of fullness after eating), abdominal discomfort, and vomiting may have bile reflux **gastritis** (also called bilious vomiting), which is also surgically correctable. Many patients also experience weight loss.

Reactive hyperglycemia is a condition that results when blood sugar becomes too high after a meal, stimulating the release of insulin, about two hours after eating. A high-protein diet and smaller meals are advised.

Ulcers recur in a small percentage of patients after surgery for peptic ulcer, usually in the first few years. Further surgery is usually necessary.

Vitamin and mineral supplementation is necessary after gastrectomy to correct certain deficiencies,

WWW.BOOKBAZ.IR

KEY TERMS

Antrectomy—A surgical procedure for ulcer disease in which the antrum, a portion of the stomach, is removed.

Laparoscopy—The examination of the inside of the abdomen through a lighted tube, sometimes accompanied by surgery.

especially vitamin B_{12}, iron, and folate. **Vitamin D** and **calcium** are also needed to prevent and treat the bone problems that often occur. These include softening and bending of the bones, which can produce pain, and **osteoporosis**, a loss of bone mass. According to one study, the risk for spinal **fractures** may be as high as 50% after gastrectomy.

Depending on the extent of surgery, the risk for post-operative death after gastrectomy for gastric cancer has been reported as 1–3% and the risk of non-fatal complications as 9–18%.

Gastric acid determination

Definition

Gastric acid determination, also known as stomach acid determination, gastric analysis, or basal gastric secretion, is a procedure to evaluate gastric (stomach) function. The test specifically determines the presence of gastric acid, as well as the amount of gastric acid secreted. It is often done in conjunction with the gastric acid stimulation test, a procedure that measures gastric acid output after injection of a drug to stimulate gastric acid secretion.

Purpose

The purpose of the gastric acid determination is to evaluate gastric function by measuring the amount of acid as suctioned directly from the stomach. The complete gastric acid determination includes the basal gastric secretion test, which measures acid secretion while the patient is in a **fasting** state (nothing to eat or drink), followed by the gastric acid stimulation test, which measures the secretion of gastric acid for one hour after injection of pentagastrin or a similar drug that stimulates gastric acid output. The Gastric acid stimulation test is done when the basal secretion test suggests abnormalities in gastric secretion. It is normally performed immediately afterward.

The basal gastric secretion test is indicated for patients with obscure gastric **pain**, loss of appetite, and weight loss. It is also utilized for suspected peptic (related to the stomach) ulcer, severe stomach inflammation (**gastritis**), and Zollinger-Ellison (Z-E) syndrome (a condition in which a pancreatic tumor, called a **gastrinoma**, stimulates the stomach to secrete excessive amounts of acid, resulting in peptic **ulcers**). Because external factors like the sight or odor of food, as well as psychological **stress**, can stimulate gastric secretion, accurate testing requires that the patient be relaxed and isolated from all sources of sensory stimulation. Abnormal basal secretion can suggest various gastric and duodenal disorders, so further evaluation requires the gastric acid stimulation test.

The gastric acid stimulation test is indicated when abnormalities are found during the basal secretion test. These abnormalities can be caused by a number of disorders, including duodenal ulcer, **pernicious anemia**, and gastric cancer. The test will detect abnormalities, but x rays and other studies are necessary for a definitive diagnosis.

Precautions

Because both the basal gastric secretion test and the gastric acid stimulation test require insertion of a gastric tube (intubation) through the mouth or nasal passage, neither test is recommended for patients with esophageal problems, **aortic aneurysm**, severe gastric hemorrhage, or **congestive heart failure**. The gastric acid stimulation test is also not recommended in patients who are sensitive to pentagastrin (the drug used to stimulate gastric acid output).

Description

This test, whether performed for basal gastric acid secretion, gastric acid stimulation, or both, requires the passage of a lubricated rubber tube, either by mouth or through the nasal passage, while the patient is in a sitting or reclining position on the left side. The

tube is situated in the stomach, with proper positioning confirmed by fluoroscopy or x ray.

Basal gastric acid secretion

After a wait of approximately 10–15 minutes for the patient to adjust to the presence of the tube, and with the patient in a sitting position, specimens are obtained every 15 minutes for a period of 90 minutes. The first two specimens are discarded to eliminate gastric contents that might be affected by the stress of the intubation process. The patient is allowed no liquids during the test, and saliva must be ejected to avoid diluting the stomach contents.

The four specimens collected during the test constitute the *basal acid output*. If analysis suggests abnormally low gastric secretion, the gastric acid stimulation test is performed immediately afterward.

Gastric acid stimulation test

After the basal samples have been collected, the tube remains in place for the gastric acid stimulation test. Pentagastrin, or a similar drug that stimulates gastric acid output, is injected under the skin (subcutaneously). After 15 minutes, a specimen is collected every 15 minutes for one hour. These specimens are called the *poststimulation specimens*. As is the case with the basal gastric secretion test, the patient can have no liquids during this test, and must eject saliva to avoid diluting the stomach contents.

Preparation

The patient should be fasting (nothing to eat or drink after the evening meal) on the day prior to the test, but may have water up to one hour before the test. **Antacids**, anticholinergics, cholinergics, alcohol, H_2-receptor antagonists (Tagamet, Pepcid, Axid, Zantac), reserpine, adrenergic blockers, and adrenocorticosteroids should be withheld for one to three days before the test, as the physician requests. If pentagastrin is to be administered for the gastric acid secretion test, medical supervision should be maintained, as possible side effects may occur.

Aftercare

Complications such as nausea, **vomiting**, and abdominal distention or pain are possible following removal of the gastric tube. If the patient has a **sore throat**, soothing lozenges may be given. The patient may also resume the usual diet and any medications that were withheld for the test(s).

KEY TERMS

Achlorhydria—An abnormal condition in which hydrochloric acid is absent from the secretions of the gastric glands in the stomach.

Pernicious anemia—One of the main types of anemia, caused by inadequate absorption of vitamin B_{12}. Symptoms include tingling in the hands, legs, and feet, spastic movements, weight loss, confusion, depression, and decreased intellectual function.

Zollinger-Ellison syndrome—A rare condition characterized by severe and recurrent peptic ulcers in the stomach, duodenum, and upper small intestine, caused by a tumor, or tumors, usually found in the pancreas. The tumor secretes the hormone gastrin, which stimulates the stomach and duodenum to produce large quantities of acid, leading to ulceration. Most often cancerous, the tumor must be removed surgically; otherwise total surgical removal of the stomach is necessary.

Results

Reference values for the *basal gastric secretion test* vary by laboratory, but are usually within the following ranges:

- men: 1–5 mEq/h
- women: 0.2–3.8 mEq/h

Reference values for the *gastric acid stimulation test* vary by laboratory, but are usually within the following ranges:

- men: 18–28 mEq/h
- women: 11–21 mEq/h

Risks

There is a slight risk that the gastric tube may be inserted improperly, entering the windpipe (trachea) and not the esophagus. If this happens, the patient may have a difficult time breathing or may experience a coughing spell until the tube is removed and reinserted properly. Also, because the tube can be difficult to swallow, if a patient has an overactive gag reflex, there may be a transient rise in blood pressure due to **anxiety**.

Abnormal

Abnormal findings in the *basal gastric secretion test* are considered nonspecific and must be evaluated in conjunction with the results of a gastric acid stimulation test. Elevated secretion may suggest different types of ulcers; when markedly elevated, Zollinger-Ellison

WWW.BOOKBAZ.IR

syndrome is suspected. Depressed secretion can indicate gastric cancer, while complete absence of secretion (achlorhydria) may suggest pernicious anemia.

Elevated gastric secretion levels in the gastric acid stimulation test may be indicative of duodenal ulcer; high levels of secretion again suggest Zollinger-Ellison syndrome.

Gastric bypass

Definition

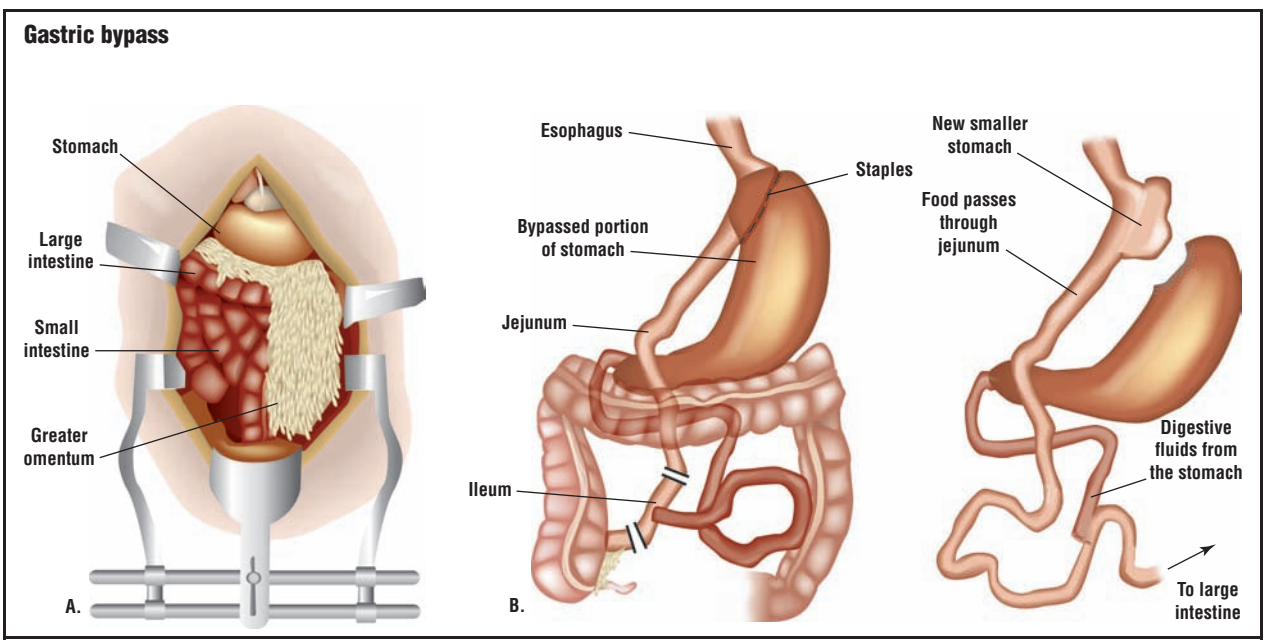
A gastric bypass is one type of elective bariatric (weight loss) surgery done on the digestive system to promote weight loss in people who are seriously obese. Gastric bypass surgery is also called malabsorptive surgery because it creates an alternate route for food traveling through the digestive system that bypasses a section of the small intestine where many nutrients are absorbed.

Purpose

Gastric bypass surgery is intended to treat severe (morbid) **obesity** in people who have tried unsuccessfully to lose weight and whose excess weight threatens their health and well-being. Obesity is defined by the **body mass index** (BMI). The BMI calculation compares weight to height. Adults age 20 and older are evaluated as follows:

- BMI below 18.5: underweight
- BMI 18.5–24.9: normal weight
- BMI 25.0–29.9: overweight
- BMI 30 and above: obese
- BMI 40 and above: morbidly or severely obese

Obesity is linked to an increased likelihood of developing over 20 different diseases and disorders, including high blood pressure (**hypertension**), type 2 diabetes, **heart disease**, **stroke**, deep vein **blood clots**, fatty **liver disease**, **sleep apnea**, **heartburn**, **gastroesophageal reflux disease** (GERD), gallstone disease, arthritis, **colon cancer**, breathing problems, and depression. Gastric bypass surgery reduces the amount of nutrients that are absorbed from food. It is



In this Roux-en-Y gastric bypass, a large incision is made down the middle of the abdomen (A). The stomach is separated into two sections. Most of the stomach will be bypassed, so food will no longer go to it. A section of jejunum (small intestine) is then brought up to empty food from the new smaller stomach (B). Finally, the surgeon connects the duodenum to the jejunum, allowing digestive secretions to mix with food further down the jejunum. *(Illustration by PreMediaGlobal. © Cengage Learning®.)*

performed in conjunction with bariatric restriction surgery in which the size of the stomach is reduced through surgical application of a band or stomach staples that close off a portion of the stomach. People who have had restriction surgery can eat only small amounts at a time before feeling full. Reduced food intake along with reduced nutrient absorption can lead to dramatic weight loss.

Demographics

Obesity is the second leading cause (after tobacco use) of preventable death in the United States. The number of overweight and obese Americans has steadily increased since 1960. According to the National Institutes of Health, in 2012, 34% of Americans were overweight and 34% were obese. In the United States, about 200,000 people have some type of weight-loss surgery each year.

The total number of surgical weight-loss procedures performed each year has increased rapidly. In 1995, only 20,000 weight-loss surgeries were performed in the United States. By 2006, 170,000 of these surgeries were done, and by 2012, the number had increased to over 200,000. In 2006, the U.S. government agreed to pay for certain bariatric surgeries for individuals who qualified for Medicare. At that time, about 395,000 Americans ages 65–69 were medically eligible for obesity surgery. This number was expected to grow to 475,000 persons by 2010. With Medicare coverage, it is likely that more older people will have weight-loss surgery. In 2006, the average patient having **bariatric surgery** was a woman in her late 30s who weighed about 300 lb. (135 kg). The procedure is controversial for people under age 18.

Description

A board-certified bariatric surgeon or a general surgeon who has specialized in the surgical treatment of obesity performs gastric bypass surgery. An anesthesiologist is responsible for administering anesthesia. The operation is performed in a hospital setting. A registered dietitian usually provides dietary counseling before and after the procedure.

There are several variations on gastric bypass, but all are malabsorptive surgeries designed to lower caloric intake by reducing the amount of nutrients absorbed by the digestive system. These include:

- gastric bypass with long gastrojejunostomy
- Roux-en-Y (RNY) gastric bypass
- transected (Miller) RNY bypass
- laparoscopic RNY bypass
- vertical (Fobi) gastric bypass
- distal RNY bypass
- biliopancreatic (BPD) diversion

All bariatric procedures create an alternate route for food through the digestive system so that the food bypasses part of the intestine. These procedures are accompanied by a reduction in the size of the stomach so that less food can be consumed comfortably. The choice of procedure depends on the patient's overall health status and on the surgeon's judgment and experience.

In the operating room, the patient is put under general **anesthesia** by the anesthesiologist. Once the patient is asleep, an endotracheal tube is placed through the mouth into the trachea (windpipe) to connect the patient to a respirator during surgery. A urinary catheter is placed in the bladder to drain urine during surgery and for the first two days after surgery. This also allows the surgeon to monitor the patient's hydration. A nasogastric (NG) tube is placed through the nose to drain secretions and is typically removed the morning after surgery.

Roux-en-Y

The most common gastric bypass operation is the Roux-en-Y (RNY) gastric bypass. In this surgery, a small stomach pouch is created by stapling and banding the stomach. The pouch is about the size of an egg and initially can hold 1–2 oz (30–60 mL), as compared to the 40–50 oz (1.2–1.5 L) held by a normal stomach. It is created along the more muscular side of the stomach, which makes it less likely to stretch over time.

Next, a Y-shaped piece of intestine is attached to the pouch on one end, and to the jejunum, or middle part of the small intestine, on the other. This allows food to bypass the duodenum, or first part of the small intestine, where nutrients are absorbed. The food then continues normally through the rest of the small intestine and the large intestine.

The RNY gastric bypass can also be performed laparoscopically. The result is the same as an open surgery RNY, except that instead of opening the patient with a long incision on the stomach, surgeons make a small incision and insert a pencil-thin optical instrument called a laparoscope that guides the surgeon via output to a TV monitor. The laparoscopic RNY results in smaller **scars**, as usually only three to four small incisions are made. The average time required to complete the laparoscopic RNY gastric bypass is approximately two hours.

WWW.BOOKBAZ.IR

The great advantage of the Roux-en-Y gastric bypass is that individuals lose, on average, 60–70% of their excess weight and are able to maintain the weight loss for ten years or more. As a result, most obesity-related health problems are substantially reduced or cured when weight is lost and that weight loss is maintained.

However, Roux-en-Y surgery also has some serious disadvantages, including:

- The surgery is more difficult for the surgeon than restrictive surgeries, and involves permanently altering the digestive system.
- Many vitamins and minerals are absorbed in the part of the small intestine bypassed by this surgery. The individual must commit to a lifetime of taking nutritional supplements to prevent serious vitamin and mineral deficiencies.
- Tearing, bleeding, and infection at the incision and reconnection sites can be potentially fatal complications.
- Dumping syndrome may occur in response to meals high in sugar. Dumping occurs when food moves too fast through the intestine and causes symptoms of nausea, bloating, weakness, sweating, fainting, and diarrhea.

Biliopancreatic diversion

Biliopancreatic diversion (BPD), another type of malabsorptive surgery, bypasses an even longer section of the small intestine. In BPD, about two-thirds of the stomach is surgically withdrawn, leaving a pouch that can hold about three cups of food. A bypass is then created to the ileum, or final portion of the small intestine. In all, about 9 ft (3 m) of intestine are bypassed. As a result, fewer calories and nutrients are absorbed. The main advantage of BPD is the large amount of excess weight—75–80%—that is lost over the first two years and the health benefits that this loss brings. Disadvantages are the same as for Roux-en-Y surgery, but nutrient deficiencies are greater. Because fat is poorly digested as a result of this surgery, bowel movements are frequent and stools are especially foul smelling.

Diagnosis

A diagnosis of obesity relies on a body weight assessment based on the body mass index (BMI) and waist circumference measurements. Waist circumference exceeding 40 in (101 cm) in men or 35 in (89 cm) in women increases disease risk. Gastric bypass as a weight-loss treatment is considered only for morbidly obese patients whose health is impaired by their obesity. To be candidates for gastric bypass surgery, individuals need to have failed at serious attempts to lose weight in the past, be in good mental health, demonstrate an understanding of the risks associated with this surgery, and be willing to make a lifetime commitment to changing eating habits.

Preparation

Before the surgery, the patient will undergo a physical and psychological examination and receive nutritional counseling. To prepare for the surgery itself, an intravenous (IV) line is placed, and the patient may be given a sedative to help relax before going to the operating room.

Aftercare

Patients can expect to experience postoperative **pain** and the other common discomforts of major surgery, such as the NG tube and a **dry mouth**. Pain is managed with medication. A large dressing covers the surgical incision on the abdomen of the patient and is usually removed by the second day in the hospital. Short showers 48 hours after surgery are usually allowed. Patients are also fitted with special socks to improve blood flow in their legs and prevent blood clot formation. At the surgeon's discretion, some patients may have a **gastrostomy** tube (g-tube) inserted during surgery to drain secretions from the larger bypassed portion of the stomach. After a few days, it will be clamped and will remain closed. When inserted, the g-tube usually remains for another four to six weeks. It is kept in place in the unlikely event that the patient may need direct feeding into the stomach.

By the evening after surgery or the next day at the latest, patients are usually able to sit up or walk around. Gradually, physical activity may be increased, with normal activity resuming three to four weeks after surgery. Patients are also taught breathing exercises and are asked to **cough** frequently to clear their lungs of mucus. Postoperative pain medication is prescribed to ease discomfort and is initially administered by an epidural. At the time patients are discharged from the hospital, they will be given oral medications for pain. Most patients will typically have a three-day hospital stay if their surgery is uncomplicated.

After gastric bypass or BPD, the individual does not eat anything for one or two days, giving the bowel time to rest. During this time, all **nutrition** is given

intravenously. Once the person begins eating, the initial diet includes:

- liquids such as juice, broth, milk, or diluted cooked cereal for two or three days
- pureed foods that have the texture of baby food for two or three weeks while the stomach heals; these foods must be smooth and contain no large pieces
- soft foods such as ground meat and soft-cooked fruits and vegetables for about eight weeks
- regular foods in very small amounts

Most people begin by eating six tiny meals a day. These meals should be high in protein. Food must be chewed thoroughly. Liquids are drunk between meals, not with them.

People who have gastric bypass surgery or BPD need extensive nutritional counseling and must take vitamin and mineral supplements for the rest of their lives. Most iron and **calcium** is absorbed in the duodenum, the first part of the intestine that is bypassed by these operations. Calcium deficiency can lead to **osteoporosis**, and iron deficiency can cause anemia.

In BPD, only 25% of the fat in food is absorbed because so much of the small intestine is bypassed. The fat-soluble **vitamins** A, D, E, and K are absorbed along with fat. When the body absorbs too little fat, inadequate amounts of these fat-soluble vitamins are absorbed, so dietary supplements containing these vitamins must be taken. Other vitamins that may not be absorbed in adequate amounts are vitamin B_{12}, **folic acid**, and vitamin B_1 (thiamine).

Results

Most people who have surgery for obesity lose anywhere from 50–80% of their excess weight. However, quite a few put pounds back on beginning several years after surgery. The main reason for weight gain is noncompliance with their nutrition and **exercise** plan. Also, over time the size of the stomach pouch in restrictive surgeries tends to stretch, allowing people to eat more and still feel comfortable. On the positive side, people who lose weight through surgery almost always see great improvement in any obesity-related diseases they may have.

Risks

Gastric bypass surgery has many of the same risks associated with other major abdominal operations. Life-threatening complications or death are rare, occurring in less than 1% of patients. Significant side effects, such as wound healing problems, difficulty in swallowing food, infections, and extreme nausea, can occur in 10%–20% of patients. Blood clots after major surgery are rare, but extremely dangerous; if they occur, they may require rehospitalization and anticoagulant (blood-thinning) medications.

Some risks are specific to gastric bypass surgery:

- Dumping syndrome usually occurs when sweet foods are eaten or when food is eaten too quickly. When the food enters the small intestine, it causes cramping, sweating, and nausea.
- Abdominal hernias are the most common complications and require follow-up surgery. Incisional hernias occur in 10%–20% of patients and require follow-up surgery.
- The stoma, or opening between the stomach and intestines, can sometimes become too narrow, causing vomiting. The stoma can be repaired by an outpatient procedure that uses a small endoscopic balloon to stretch it.
- Gallstones develop in more than one-third of obese patients undergoing gastric surgery. Gallstones are clumps of cholesterol and other matter that accumulate in the gallbladder. Rapid or major weight loss increases a person's risk of developing gallstones.
- Leakage of stomach and intestinal contents from the staple and suture lines into the abdomen can occur. This is a rare occurrence and sometimes seals itself. If not, another operation is required.

Research published in the journal *Neurology* in March 2007 found that a very small number of people developed a brain disorder called Wernicke's **encephalopathy** 4–12 weeks after bariatric surgery. This disorder is caused by a deficiency of vitamin B_1. Most of the people who developed the disorder had failed to take their vitamin supplements as prescribed after surgery.

Alternatives

Lap-band and adjustable gastric band restrictive surgery used alone represent alternatives to gastric bypass surgery. Lap-band surgery achieves restriction by placing a saline (salt water) filled bag around the stomach, pinching off a portion of it and leaving only a small pouch at the top. The exit to the pouch is narrowed so that the rate at which the pouch empties is slowed. Because the pouch is so small, the individual can only eat about half a cup of food at a time without feeling nauseated. Since there is no cutting, stapling, or stomach rerouting involved, the procedure is the least invasive of all weight-loss surgeries. Patients generally experience less pain and scarring, and their hospital stay is shorter than with malabsorptive surgeries. In addition, a port allows access to the saline bag, so that

WWW.BOOKBAZ.IR

the size of the stomach pouch can be adjusted without additional surgery. This surgery is reversible; the band or saline bag can be removed and the digestive system will function normally. Weight loss averages 50–65% of the excess body weight during the first two years. The procedure is often covered by Medicare.

Gastric band surgery uses a different technique to reduce the size of the stomach. The U.S. Food and Drug Administration (FDA) approved this surgery in 2001. Its long-term effects have not been studied.

Vertical banded gastroplasty (VBG) is also known as stomach stapling. This surgery is performed less often than lap-band surgery. With VBG, part of the stomach is stapled shut, making it smaller so that individuals feel full sooner. The advantage of VBG is that the procedure is quick and has few complications. Disadvantages are that the average weight loss is less than with other weight-loss surgeries, and staples can pull out, allowing small leaks between the stomach and the abdomen to develop. Infection is possible but rare (less than 1%).

Nonsurgical

Diet and nutrition counseling is the main nonsurgical method of weight loss. Diet therapy involves instruction on how to adjust diet to reduce the number of calories eaten. Reducing calories moderately is essential in achieving gradual and steady weight loss, and in maintaining the loss. Strategies of diet and nutrition therapy include teaching individuals about the calorie content of different foods, food composition (fats, carbohydrates, and proteins), reading nutrition labels, types of foods to buy, and how to prepare foods. To be healthful, a diet must provide balanced nutrition along with calorie reduction.

Physical activity, especially when combined with a healthy low-calorie diet, is another nonsurgical way to lose weight. Moderate physical activity, progressing to 30 minutes or more five or more days a week, is recommended for weight loss. Physical activity has also been reported to be a key part of maintaining weight loss. Abdominal fat and, in some cases, waist circumference can be modestly reduced through physical activity. Strategies of successful weight loss through long-term physical activity involve selecting enjoyable activities that can be scheduled into a regular daily routine.

Behavior therapy aims to improve diet and physical activity patterns and to help people develop new habits and behaviors that promote weight loss. Behavioral therapy strategies for weight loss and maintenance include keeping a food and exercise diary; identifying high-risk situations, such as having high-calorie foods in the house, and learning to avoiding these situations; using non-food rewards for specific actions, such as exercising regularly; developing realistic goals; modifying false beliefs about weight loss and **body image**; developing a social support network (family, friends, or colleagues); and joining a support group that will encourage weight loss in a positive and motivating manner.

Drug therapy is another nonsurgical alternative option for treating obesity. The U.S. Food and Drug Administration (FDA) has approved several prescription drugs for treating obesity, including orlistat (Xenical), phentermine (an appetite suppressant available under more than a dozen trade names), phentermine and topiramate extended-release (Qsymia), and lorcaserin (Belviq). Sibutramine (Meridia in the United States, Reductil in Europe) was voluntarily withdrawn from the U.S. market in October 2010 over concerns that it increased the risk of **heart attack** and stroke. In 2007, orlistat became available in the United States as an over-the-counter (nonprescription) drug under the name Alli. Use of these drugs does not negate the need for calorie reduction and regular exercise.

KEY TERMS

Gastrojejunostomy—A surgical procedure in which the stomach is surgically connected to the jejunum (middle portion of the small intestine).

Hernia—The protrusion of a loop or section of an organ or tissue through an abnormal opening.

Laparoscopy—The examination of the inside of the abdomen through a lighted tube (endoscope), sometimes accompanied by surgery done through a small incision.

Malabsorption—Poor absorption of materials in the digestive system.

Morbidly obese—A term used to describe individuals either 100 lb. (45 kg) or more than 50% overweight and/or who have a body mass index above 40.

Small intestine—Consists of three sections: duodenum (nearest the stomach), jejunum, and ileum (nearest the colon or large intestine). Different nutrients are absorbed in different sections of the small intestine.

Gastric carcinoma *see* **Stomach cancer**

Gastric emptying scan

Definition

A gastric emptying scan (GES) is an x-ray exam using special radioactive material that allows physicians to identify abnormalities related to emptying of the stomach. Diseases that involve changes in the way the stomach contracts (motility disorders) are best diagnosed by this test.

Purpose

The study is used most frequently to evaluate patients who have symptoms suggestive of decreased, delayed, or rapid gastric emptying, and no visible abnormality to explain their symptoms.

Symptoms pointing to a delay in gastric emptying are non-specific, and may be due to a number of causes, such as **ulcers**, diabetes, tumors, and others. These symptoms include nausea, upper abdominal bloating, and at times **vomiting**. Another significant symptom is called "early satiety," which means feeling full after eating only a small amount of food. In some patients, weight loss is also present. In addition to symptoms, the finding of a large amount of material in the stomach after an overnight fast suggests abnormal emptying, but does not distinguish between an actual blockage or an irregularity in gastric contractions. It is therefore essential to find out what is causing material to remain in the stomach.

Since many diseases can produce the above symptoms, structural lesions (such as tumors or regions of narrowing or scar tissue) need to be ruled out first. This is usually done by upper gastrointestinal series test or by **endoscopy** (examination of the inside of an organ, in

WWW.BOOKBAZ.IR

this instance the stomach, with an instrument that has a light at the end of it and an optical system for examination of the organ). Once it is clear that a mechanical or physical lesion is not the cause of symptoms, attempts to document an abnormality in the nervous or muscular function of the stomach is then begun. GES is usually the first step in that evaluation.

Precautions

The exam should not be performed on pregnant women, but is otherwise quite safe. Since eggs are usually used to hold the radioactive material, patients should notify their physician if they are allergic to eggs. However, other materials can be used in place of an egg.

Description

Gastric emptying scans have undergone several changes since the initial studies in the late 1970s. During the study, patients are asked to ingest an egg sandwich containing a radioactive substance (for example, technetium) that can be followed by a special camera. The emptying of the material from the stomach is then followed and displayed both in the form of an image, as well as the percentage emptied over several hours (generally two and four hours). Studies are in progress using substances that are not radioactive, but this procedure is not available to the patient as of yet.

Preparation

The only preparation involved is for the patient to fast overnight before the test.

Results

There are several different measurements considered normal, depending on the radioactive material and solid meal used. The value is expressed as a percentage of emptying over a period of time. For a technetium-filled egg sandwich, normal emptying is 78 minutes for half the material to leave the stomach, with a variation of 11 minutes either way.

Abnormal

GES scan studies that show emptying of the stomach in a longer than accepted period is abnormal. Severity of test results and symptoms do not always match; therefore, the physician must carefully interpret these findings. Diabetic injury to the nerves that supply the stomach (called diabetic gastroparesis) is one of the most common causes of abnormal gastric motility. However, up to 30% of patients have no obvious cause to explain the abnormal results and symptoms. These cases are called idiopathic (of unknown cause). GES is often used to follow the effect of medications used for treatment of motility disorders.

KEY TERMS

Endoscopy—The examination of the inside of an organ with an instrument that has a light at the end of it and an optical system for examination of the organ.

Motility—Motility is spontaneous movement. One example is the automatic stomach contractions that move the food content along from the stomach into the intestines. A motility disease is one that involves changes in the way the stomach contracts.

Risks

The radiation exposure during the study is quite small and safe, unless the patient is pregnant.

Gastrinoma

Definition

Gastrinomas are tumors associated with a rare gastroenterological disorder known as Zollinger-Ellison syndrome (ZES). They occur primarily in the pancreas and duodenum (beginning of the small intestine) and secrete large quantities of the hormone gastrin, triggering gastric acid production that produces **ulcers**. They may be malignant (cancerous) or benign.

Description

Gastrinomas are an integral part of the Zollinger-Ellison syndrome (ZES). In fact, ZES is also known as gastrinoma. This syndrome consists of ulcer disease in

the upper gastrointestinal tract, marked increases in the secretion of gastric acid in the stomach, and tumors of the islet cells in the pancreas. The tumors produce large amounts of gastrin that are responsible for the characteristics of Zollinger-Ellison syndrome, namely severe ulcer disease. Although usually located within the pancreas, they may occur in other organs.

Gastrinomas may occur randomly and sporadically, or they may be inherited as part of a genetic condition called multiple endocrine neoplasia type 1 (MEN-1) syndrome. About half of persons with MEN-1 have gastrinomas, which tend to be more numerous and smaller than tumors in sporadic cases.

About half of ZES patients have multiple gastrinomas, which can vary in size from 1 to 20 mm. Gastrinomas found in the pancreas are usually much larger than duodenal gastrinomas. About two thirds of gastrinomas are malignant (cancerous). These usually grow slowly, but some may invade surrounding sites rapidly and metastasize (spread) widely. Sometimes, gastrinomas are found only in the lymph nodes, and it is uncertain whether these malignancies have originated in the lymph nodes or have metastasized from a tumor not visible in the pancreas or duodenum.

There is some evidence that the more malignant form of gastrinomas is more frequent in larger pancreatic tumors, especially in females and in persons with a shorter disease symptom duration and higher serum gastrin levels.

Causes and symptoms

Most persons with gastrinomas secrete profound amounts of gastric acid, and almost all develop ulcers, mostly in the duodenum or stomach. Early in the course of the disease, symptoms are typical of peptic ulcers, however once the disease is established, the ulcers become more persistent and symptomatic, and may respond poorly to standard anti-ulcer therapy. Abdominal **pain** is the predominant symptom of ulcer disease. About 40% of patients have **diarrhea** as well. In some patients, diarrhea is the primary symptom of gastrinoma.

Diagnosis

Persons with gastrinomas have many of the same symptoms as persons with ulcers. Their levels of gastric acid, however, are usually far greater than those in common ulcer disease. Gastrinomas are usually diagnosed by a blood test that measures the level of gastrin in the blood. Patients with gastrinomas often have gastrin levels more than 200 pg/mL, which is 4–10 times higher than normal. Serum gastrin levels as high as 450,000 pg/mL have occurred.

When the serum gastrin test does not show these extremely high levels of gastrin, patients may be given certain foods or injections in an attempt to provoke a response that will help diagnose the condition. The most useful of these provocative tests is the secretin injection test (or secretin stimulation or provocative test), which will almost always produce a positive response in persons with gastrinomas but seldom in persons without them.

Surgically, gastrinomas are often difficult to locate, even with careful inspection. They may be missed in at least 10–20% of patients with ZES. Gastrinomas are sometimes found only because they have metastasized and produced symptoms related to the spread of malignancy. Such metastasis may be the most reliable indication of whether the gastrinoma is malignant or benign.

Diagnostic imaging techniques help locate the gastrinomas. The most sophisticated is an x-ray test called radionuclide octreotide scanning (also known as somatostatin receptor scintigraphy or 111In pentetreotide SPECT). A study by the National Institutes of Health (NIH) found this test to be superior to other imaging methods, such as computed tomography scan (CT) or **magnetic resonance imaging** (MRI), in pinpointing the location of tumors and guiding physicians in treatment.

Approximately half of all gastrinomas do not show up on imaging studies. Therefore, exploratory surgery is often recommended to try to locate and remove the tumors.

Treatment

Therapy for gastrinomas should be individualized, since patients tend to have varying degrees of disease and symptoms. Treatment is aimed at eliminating the overproduction of gastric acid and removing the gastrin-producing tumors.

Drugs

Gastrinomas may not be easily treated by the standard anti-ulcer approaches. The medical treatment of choice is with drugs called **proton pump inhibitors**, such as omeprazole or lansoprazole, daily. These drugs are potent inhibitors of gastric acid. High doses of H-2 receptor antagonists may also reduce gastric acid secretion, improve symptoms, and induce ulcer healing. These drugs must be continued indefinitely, since even a brief discontinuation will cause

WWW.BOOKBAZ.IR

KEY TERMS

Gastrin—A hormone secreted in the stomach that is involved in the production of gastric acid. Overproduction of gastric acid contributes to peptic ulcer formation.

Multiple endocrine neoplasia type 1 (MEN-1)—An inherited condition marked by multiple malignancies of the pituitary gland, parathyroid gland, and islet cells of the pancreas. About half of MEN-1 patients with pancreatic islet cell tumors will have gastrinomas, gastrin-producing tumors that lead to ulcer disease.

Peptic ulcer—An eroded area in the stomach lining or in the first part of the duodenum (beginning of the small intestine).

Serum gastrin test—A laboratory test that is performed on a blood sample to determine that level of the hormone gastrin. High levels of gastrin indicate the presence a duodenal ulcer or a gastrinoma.

Sporadic—Occurring at random or by chance, and not as a result of a genetically determined, or inherited, trait.

ulcer recurrence. **Antacids** may provide some relief, but it is usually not longlasting or healing.

Surgery

Because of the likelihood that gastrinomas may be malignant, in both sporadic tumors and those associated with the inherited MEN-1 syndrome, surgery to locate and remove gastrinomas is frequently advised. It is now known that complete surgical removal of gastrinomas can cure the overproduction of gastrin, even in patients who have metastases to the lymph nodes. Surgery in patients with MEN-1 and ZES, however, remains controversial since the benefit is less clear.

Freedom from disease after surgery is judged by improved symptoms, reduced gastric acid production, reduced need for drug therapy, normalization of serum gastrin levels, and normalization of results from the secretin stimulation test and imaging studies.

Prognosis

Medical therapy often controls symptoms, and surgery may or may not cure gastrinoma. About 50% of ZES patients in whom gastrinomas are not removed will die from malignant spread of the tumor. In patients with gastrinomas as part of MEN-1 syndrome, the cure rate is extremely low.

A NIH study of patients who had surgical removal of gastrinomas found that 42% were disease-free one year after surgery and 35% were disease-free at five years. Disease recurrences can often be detected with a serum gastrin test or secretin stimulation test.

When gastrinomas are malignant, they often grow slowly. The principal sites of metastasis are the regional lymph nodes and liver, but they may also spread to other structures. About one quarter of patients with gastrinomas have liver metastases at the time of diagnosis. This appears to be more frequent with pancreatic gastrinomas than duodenal gastrinomas.

Metastases of malignant gastrinomas to the liver is very serious. Survival five years after diagnosis is 20–30%, however patients with gastrinomas found only in the lymph nodes have been known to live as long as 25 years after diagnosis, without evidence of further tumor spread. In fact, the life expectancy of patients with gastrinomas that have spread to the lymph nodes is no different from that of patients with gastrinomas that cannot even be found at surgery for about 90%, five years after diagnosis.

Caroline A. Helwick

Gastritis

Definition

Gastritis commonly refers to inflammation of the lining of the stomach, but the term is often used to cover a variety of symptoms resulting from stomach lining inflammation and symptoms of burning or discomfort. True gastritis comes in several forms and is diagnosed using a combination of tests. In the 1990s, scientists discovered that the main cause of true gastritis is infection from a bacterium called *Helicobacter pylori* (*H. pylori*).

Description

Gastritis should not be confused with common symptoms of upper abdominal discomfort. It has been

associated with resulting **ulcers**, particularly peptic ulcers. And in some cases, chronic gastritis can lead to more serious complications.

Nonerosive H. pylori gastritis

The main cause of true gastritis is *H. pylori* infection. *H. pylori* is indicated in an average of 90% of patients with chronic gastritis. This form of nonerosive gastritis is the result of infection with *Helicobacter pylori* bacterium, a microorganism whose outer layer is resistant to the normal effects of stomach acid in breaking down bacteria.

The resistance of *H. pylori* means that the bacterium may rest in the stomach for long periods of times, even years, and eventually cause symptoms of gastritis or ulcers when other factors are introduced, such as the presence of specific genes or ingestion of **nonsteroidal anti-inflammatory drugs** (NSAIDS). Study of the role of *H. pylori* in development of gastritis and peptic ulcers has disproved the former belief that **stress** lead to most stomach and duodenal ulcers and has resulted in improved treatment and reduction of stomach ulcers. *H. pylori* is most likely transmitted between humans, although the specific routes of transmission are continuously under study.

Erosive and hemorrhagic gastritis

After *H. pylori*, the second most common cause of chronic gastritis is use of nonsteroidal anti-inflammatory drugs. These commonly used **pain** killers, including **aspirin**, fenoprofen, ibuprofen and naproxen, among others, can lead to gastritis and peptic ulcers. Other forms of erosive gastritis are those due to alcohol and corrosive agents or due to **trauma** such as ingestion of foreign bodies.

Other forms of gastritis

Clinicians differ on the classification of the less common and specific forms of gastritis, particularly since there is so much overlap with *H. pylori* in development of chronic gastritis and complications of gastritis. Other types of gastritis that may be diagnosed include:

- Acute stress gastritis—the most serious form of gastritis which usually occurs in critically ill patients, such as those in intensive care. Stress erosions may develop suddenly as a result of severe trauma or stress to the stomach lining.
- Atrophic gastritis is the result of chronic gastritis which is leading to atrophy, or decrease in size and wasting away, of the gastric lining. Gastric atrophy is the final stage of chronic gastritis and may be a precursor to gastric cancer.
- Superficial gastritis is a term often used to describe the initial stages of chronic gastritis.
- Uncommon specific forms of gastritis include granulomatous, eosiniphilic and lymphocytic gastritis.

Causes and symptoms

Nonerosive H. pylori gastritis

H. pylori gastritis is caused by infection from the *H. pylori* bacterium. The route of its transmission is under study as clinicians believe there are numerous routes for the bacterium. Its prevalence and distribution differs in nations around the world. The presence of *H. pylori* has been detected in 86–99% of patients with chronic superficial gastritis. However, physicians are still learning about the link of *H. pylori* to chronic gastritis and peptic ulcers, since many patients with *H. pylori* infection do not develop symptoms or peptic ulcers. *H. pylori* is also seen in 90–100% of patients with duodenal ulcers.

Symptoms of *H. pylori* gastritis include abdominal pain and reduced acid secretion in the stomach. However, the majority of patients with *H. pylori* infection suffer no symptoms, even though the infection may lead to ulcers and resulting symptoms. Ulcer symptoms include dull, gnawing pain, often two to three hours after meals and pain in the middle of the night when the stomach is empty.

Erosive and hemorrhagic gastritis

The most common cause of this form of gastritis is use of NSAIDS. Other causes may be **alcoholism** or stress from surgery or critical illness. The role of NSAIDS in development of gastritis and peptic ulcers depends on the dose level. Although even low doses of aspirin or other nonsteroidal anti-inflammatory drugs may cause some gastric upset, low doses generally will not lead to gastritis. However, as many as 10–30% of patients on higher and more frequent doses of NSAIDS, such as those with chronic arthritis, may develop gastric ulcers. Studies were underway to understand the role of *H. pylori* in gastritis and ulcers among patients using NSAIDS.

Patients with erosive gastritis may also show no symptoms. When symptoms do occur, they may include **anorexia nervosa**, gastric pain, **nausea and vomiting**.

Other forms of gastritis

Less common forms of gastritis may result from a number of generalized diseases or from complications of chronic gastritis. Any number of mechanisms may

WWW.BOOKBAZ.IR

cause various less common forms of gastritis and they may differ slightly in their symptoms and clinical signs. However, they all have in common inflammation of the gastric mucosa.

Diagnosis

Nonerosive H. pylori gastritis

H. pylori gastritis is easily diagnosed through the use of the urea breath test. This test detects active presence of *H. pylori* infection. Other serological tests, which may be readily available in a physician's office, may be used to detect *H. pylori* infection. Newly developed versions offer rapid diagnosis. The choice of test will depend on cost, availability and the physician's experience, since nearly all of the available tests have an accuracy rate of 90% or better. **Endoscopy**, or the examination of the stomach area using a hollow tube inserted through the mouth, may be ordered to confirm diagnosis. A biopsy of the gastric lining may also be ordered.

Erosive or hemorrhagic gastritis

Clinical history of the patient may be particularly important in the diagnosis of this type of gastritis, since its cause is most often the result of chronic use of NSAIDS, alcoholism, or other substances.

Other forms of gastritis

Gastritis that has developed to the stage of duodenal or gastric ulcers usually requires endoscopy for diagnosis. It allows the physician to perform a biopsy for possible malignancy and for *H. pylori*. Sometimes, an upper gastrointestinal x-ray study with barium is ordered. Some diseases such as Zollinger-Ellison syndrome, an ulcer disease of the upper gastrointestinal tract, may show large mucosal folds in the stomach and duodenum on radiographs or in endoscopy. Other tests check for changes in gastric function.

Treatment

H. pylori gastritis

The discovery of *H. pylori's* role in development of gastritis and ulcers has led to improved treatment of chronic gastritis. In particular, relapse rates for duodenal and gastric ulcers has been reduced with successful treatment of *H. pylori* infection. Since the infection can be treated with **antibiotics**, the bacterium can be completely eliminated up to 90% of the time.

Although *H. pylori* can be successfully treated, the treatment may be uncomfortable for patients and relies heavily on patient compliance. Clinicians are attempting to identify the best treatment method based on simplicity, patient cooperation and results. As of 2014, no single antibiotic had been found which would eliminate *H. pylori* on its own, so a combination of antibiotics has been prescribed to treat the infection.

DUAL THERAPY. Dual therapy involves the use of an antibiotic and a proton pump inhibitor. **Proton pump inhibitors** help reduce stomach acid by halting the mechanism that pumps acid into the stomach. This also helps promote healing of ulcers or inflammation. Dual therapy has not been proven to be as effective as triple therapy, but may be ordered for some patients who can more comfortably handle the use of less drugs and will therefore more likely follow the two-week course of therapy.

TRIPLE THERAPY. As of early 1998, triple therapy was the preferred treatment for patients with *H. pylori* gastritis. It is estimated that triple therapy successfully eliminates 80–95% of *H. pylori* cases. This treatment regimen usually involves a two-week course of three drugs. An antibiotic such as amoxicillin or tetracycline, and another antibiotic such as clarithomycin or metronidazole are used in combination with bismuth subsalicylate, a substance found in the over-the-counter medication, Pepto-Bismol, which helps protect the lining of the stomach from acid. Physicians were experimenting with various combinations of drugs and time of treatment to balance side effects with effectiveness. Side effects of triple therapy are not serious, but may cause enough discomfort that patients are not inclined to follow the treatment.

OTHER TREATMENT THERAPIES. Scientists have experimented with quadruple therapy, which adds an antisecretory drug, or one which suppresses gastric secretion, to the standard triple therapy. One study showed this therapy to be effective with only a week's course of treatment in more than 90% of patients. Short course therapy was attempted with triple therapy involving antibiotics and a proton pump inhibitor and seemed effective in eliminating *H. pylori* in one week for more than 90% of patients. The goal is to develop the most effective therapy combination that can work in one week of treatment or less.

MEASURING H. PYLORI TREATMENT EFFECTIVENESS. In order to ensure that *H. pylori* has been eradicated, physicians will test patients following treatment. The breath test is the preferred method to check for remaining signs of *H. pylori*.

Treatment of erosive gastritis

Since few patients with this form of gastritis show symptoms, treatment may depend on severity of

symptoms. When symptoms do occur, patients may be treated with therapy similar to that for *H. pylori*, especially since some studies have demonstrated a link between *H. pylori* and NSAIDS in causing ulcers. Avoidance of NSAIDS will most likely be prescribed.

Other forms of gastritis

Specific treatment will depend on the cause and type of gastritis. These may include prednisone or antibiotics. Critically ill patients at high risk for bleeding may be treated with preventive drugs to reduce risk of acute stress gastritis. If stress gastritis does occur, the patient is treated with constant infusion of a drug to stop bleeding. Sometimes surgery is recommended, but is weighed with the possibility of surgical complications or death. Once torrential bleeding occurs in acute stress gastritis, mortality is as high as greater than 60%.

Alternatives

Alternative forms of treatment for gastritis and ulcers should be used cautiously and in conjunction with conventional medical care, particularly now that scientists have confirmed the role of *H. pylori* in gastritis and ulcers. Alternative treatments can help address gastritis symptoms with diet and **nutritional supplements**, herbal medicine and **ayurvedic medicine**. It is believed that zinc, **vitamin A** and beta-carotene aid in the stomach lining's ability to repair and regenerate itself. Herbs thought to stimulate the immune system and reduce inflammation include **echinacea** (*Echinacea* spp.) and goldenseal (*Hydrastis canadensis*). Ayurvedic medicine involves **meditation**. There are also certain herbs and nutritional supplements aimed at helping to treat ulcers.

Prognosis

The discovery of *H. pylori* has improved the prognosis for patients with gastritis and ulcers. Since treatment exists to eradicate the infection, recurrence is much less common. The only patients requiring treatment for *H. pylori* are those at high risk because of factors such as NSAIDS use or for those with ulcers and other complicating factors or symptoms. Research will continue into the most effective treatment of *H. pylori*, especially in light of the bacterium's resistance to certain antibiotics. Regular treatment of patients with gastric and duodenal ulcers has been recommended, since H. pylori plays such a consistently high role in development of ulcers. It is believed that *H. pylori* also plays a role in the eventual development of serious gastritis complications and cancer. Detection and treatment of *H. pylori* infection may help reduce occurrence of these diseases. The prognosis for patients with acute stress gastritis is much poorer, with a 60 percent or higher mortality rate among those bleeding heavily.

KEY TERMS

Duodenal—Refers to the duodenum, or the first part of the small intestine.

Gastric—Relating to the stomach.

Mucosa—The mucous membrane, or the thin layer which lines body cavities and passages.

Ulcer—A break in the skin or mucous membrane. It can fester and pus like a sore.

Prevention

The widespread detection and treatment of *H. pylori* as a preventive measure in gastritis has been discussed but not resolved. Until more is known about the routes through which *H. pylori* is spread, specific prevention recommendations are not available. Erosive gastritis from NSAIDS can be prevented with cessation of use of these drugs. An education campaign was launched in 1998 to educate patients, particularly an **aging** population of arthritis sufferers, about risk for ulcers from NSAIDS and alternative drugs.

Gastroenteritis

Definition

Gastroenteritis is a catchall term for infection or irritation of the digestive tract, particularly the stomach and intestine. It is frequently referred to as the stomach or intestinal flu, although the **influenza** virus is not associated with this illness. Major symptoms include **nausea and vomiting**, **diarrhea**, and abdominal cramps. These symptoms are sometimes also accompanied by **fever** and overall weakness. Gastroenteritis typically lasts about three days. Adults usually recover without problem, but children, the elderly, and anyone with an underlying disease are more vulnerable to complications such as **dehydration**.

Demographics

Gastroenteritis is an uncomfortable and inconvenient ailment, but it is rarely life-threatening in the United States and other developed nations. However, an estimated 220,000 children younger than age five are hospitalized with gastroenteritis symptoms in the United States annually. Of these children, 300 die as a result of severe diarrhea and dehydration. In developing nations, diarrheal illnesses are a major source of mortality. Worldwide, inadequate treatment of gastroenteritis kills 5 to 8 million people per year, and is a leading cause of death among infants and children under the age of 5. Annually, worldwide, rotaviruses are estimated to cause 800,000 deaths in children below age five.

Description

Typically, children are more vulnerable to rotaviruses, the most significant cause of acute watery diarrhea. For this reason, much research has gone into developing a vaccine to protect children from this virus. Adults can be infected with rotaviruses, but these infections typically have minimal or no symptoms. Children are also susceptible to adenoviruses and astroviruses, which are minor causes of childhood gastroenteritis. Adults experience illness from astroviruses as well, but the major causes of adult viral gastroenteritis are the caliciviruses and SRSVs. These viruses also cause illness in children. The SRSVs are a type of calicivirus and include the Norwalk, Southampton, and Lonsdale viruses. These viruses are the most likely to produce **vomiting** as a major symptom.

Bacterial gastroenteritis is frequently a result of poor sanitation, the lack of safe drinking water, or contaminated food—conditions common in developing nations. Natural or man-made disasters can make underlying problems in sanitation and food safety worse. In developed nations, the modern food production system potentially exposes millions of people to disease-causing bacteria through its intensive production and distribution methods. Common types of bacterial gastroenteritis can be linked to *Salmonella* and *Campylobacter* bacteria; however, *Escherichia coli* 0157 and *Listeria monocytogenes* are creating increased concern in developed nations. **Cholera** and Shigella remain two diseases of great concern in developing countries, and research to develop long-term vaccines against them is underway.

Causes and symptoms

Gastroenteritis arises from ingestion of viruses, certain bacteria, or parasites. Food that has spoiled may also cause illness. Certain medications and excessive alcohol can irritate the digestive tract to the point of inducing gastroenteritis. Regardless of the cause, the symptoms of gastroenteritis include diarrhea, nausea and vomiting, and abdominal **pain** and cramps. Sufferers may also experience bloating, low fever, and overall tiredness. Typically, the symptoms last only two to three days, but some viruses may last up to a week.

A usual bout of gastroenteritis shouldn't require a visit to the doctor. However, medical treatment is essential if symptoms worsen or if there are complications. Infants, young children, the elderly, and persons with underlying disease require special attention in this regard.

The greatest danger presented by gastroenteritis is dehydration. The loss of fluids through diarrhea and vomiting can upset the body's electrolyte balance, leading to potentially life-threatening problems such as heartbeat abnormalities (arrhythmia). The risk of dehydration increases as symptoms are prolonged. Dehydration should be suspected if a **dry mouth**, increased or excessive thirst, or scanty urination is experienced.

If symptoms do not resolve within a week, an infection or disorder more serious than gastroenteritis may be involved. Symptoms of great concern include a high fever (102° F [38.9°C] or above), blood or mucus in the diarrhea, blood in the vomit, and severe abdominal pain or swelling. These symptoms require prompt medical attention.

Diagnosis

The symptoms of gastroenteritis are usually enough to identify the illness. Unless there is an outbreak

affecting several people or complications are encountered in a particular case, identifying the specific cause of the illness is not a priority. However, if identification of the infectious agent is required, a stool sample will be collected and analyzed for the presence of viruses, disease-causing (pathogenic) bacteria, or parasites.

Treatment

Gastroenteritis is a self-limiting illness which will resolve by itself. However, for comfort and convenience, a person may use over-the-counter medications such as Pepto Bismol to relieve the symptoms. These medications work by altering the ability of the intestine to move or secrete spontaneously, absorbing toxins and water, or altering intestinal microflora. Some over-the-counter medicines use more than one element to treat symptoms.

If over-the-counter medications are ineffective and medical treatment is sought, a doctor may prescribe a more powerful anti-diarrheal drug, such as motofen or lomotil. Should pathogenic bacteria or parasites be identified in the patient's stool sample, medications such as **antibiotics** will be prescribed.

It is important to stay hydrated and nourished during a bout of gastroenteritis. If dehydration is absent, the drinking of generous amounts of nonalcoholic fluids, such as water or juice, is adequate. **Caffeine**, since it increases urine output, should be avoided. The traditional BRAT diet—bananas, rice, applesauce, and toast—is tolerated by the tender gastrointestinal system, but it is not particularly nutritious. Many, but not all, medical researchers recommend a diet that includes complex carbohydrates (e.g., rice, wheat, potatoes, bread, and cereal), lean meats, yogurt, fruit, and vegetables. Milk and other dairy products shouldn't create problems if they are part of the normal diet. Fatty foods or foods with a lot of sugar should be avoided. These recommendations are based on clinical experience and controlled trials, but are not universally accepted.

Minimal to moderate dehydration is treated with oral rehydrating solutions that contain glucose and electrolytes. These solutions are commercially available under names such as Naturalyte, Pedialyte, Infalyte, and Rehydralyte. Oral rehydrating solutions are formulated based on physiological properties. Fluids that are not based on these properties—such as cola, apple juice, broth, and sports beverages—are not recommended to treat dehydration. If vomiting interferes with oral rehydration, small frequent fluid intake may be better tolerated. Should oral rehydration fail or severe dehydration occur, medical treatment in the form of intravenous (IV) therapy is required. IV therapy can be followed with oral rehydration as the patient's condition improves. Once normal hydration is achieved, the patient can return to a regular diet.

KEY TERMS

Dehydration—A condition in which the body lacks the normal level of fluids, potentially impairing normal body functions.

Electrolyte—An ion, or weakly charged element, that conducts reactions and signals in the body. Examples of electrolytes are sodium and potassium ions.

Glucose—A sugar that serves as the body's primary source of fuel.

Influenza—A virus that affects the respiratory system, causing fever, congestion, muscle aches, and headaches.

Intravenous (IV) therapy—Administration of intravenous fluids.

Microflora—The bacterial population in the intestine.

Pathogenic bacteria—Bacteria that produce illness.

Probiotics—Bacteria that are beneficial to a person's health, either through protecting the body against pathogenic bacteria or assisting in recovery from an illness.

Alternatives

Symptoms of uncomplicated gastroenteritis can be relieved with adjustments in diet, herbal remedies, and homeopathy. An infusion of meadowsweet (*Filipendula ulmaria*) may be effective in reducing nausea and stomach acidity. Once the worst symptoms are relieved, slippery elm (*Ulmus fulva*) can help calm the digestive tract. Of the homeopathic remedies available, *Arsenicum album*, **ipecac**, or *Nux vomica* are three said to relieve the symptoms of gastroenteritis.

Probiotics, bacteria that are beneficial to a person's health, are recommended during the recovery phase of gastroenteritis. Specifically, live cultures of*Lactobacillus acidophilus* are said to be effective in soothing the digestive tract and returning the intestinal flora to normal. *L. acidophilus* is found in live-culture yogurt, as well as in capsule or powder form at health food stores. The use of probiotics is found in folk remedies and has some support in the medical

WWW.BOOKBAZ.IR

literature. Castor oil packs to the abdomen can reduce inflammation and also reduce spasms or discomfort.

Prognosis

Gastroenteritis is usually resolved within two to three days and there are no long-term effects. If dehydration occurs, recovery is extended by a few days.

Prevention

There are few steps that can be taken to avoid gastroenteritis. Ensuring that food is well-cooked and unspoiled can prevent bacterial gastroenteritis, but may not be effective against viral gastroenteritis.

Gastroesophageal reflux *see* **Heartburn**

Gastroesophageal reflux disease

Definition

Gastroesophageal reflux disease (GERD) is a condition in which stomach acids and other stomach contents backflow into the esophagus, the tube leading from the mouth to the stomach, causing a burning sensation in the middle of the chest known as **heartburn**.

Demographics

Estimates of the number of people in the United States with GERD may be significantly underreported because some people who experience heartburn self-treat through over-the-counter medications and are never officially diagnosed with GERD unless a more serious condition occurs. The American College of Gastroenterology estimates that about 60 million Americans experience heartburn at least once a month; of these, 15 million experience the condition daily. Other estimates suggest that 7% of the population has heartburn daily, and of these individuals, 20–40% have GERD, while heartburn in the remaining individuals arises from other causes. GERD occurs in all races and at all ages but is most common in people over age 40 years. Men and women are equally affected, although white men are ten times more likely to develop Barrett's esophagus (a precursor of **esophageal cancer**) than women.

Gastroesophageal reflux disease (GERD) relief

Diet and lifestyle modifications:

- Eat smaller but more frequent meals
- Avoid common triggers (including tomato sauces, fried or spicy foods, alcohol, and caffeinated beverages)
- Lose excess weight
- Sleep with the head elevated
- Avoid eating before bed

Over-the-counter medications:

- Antacids (Tums*, Rolaids)
- OTC acid blockers (Pepcid AC, Prilosec OTC)

Prescription medications:

- Proton pump inhibitors (Nexium, Prevacid)
- Pro-motility drugs (Propulsid)
- Prescription-strength antacids (Carafate)
- Prescription-strength H2 blockers (Zantac, Tagamet)

*Drug names are provided as examples but are not meant to be recommendations or wholly representative of the treatments available.

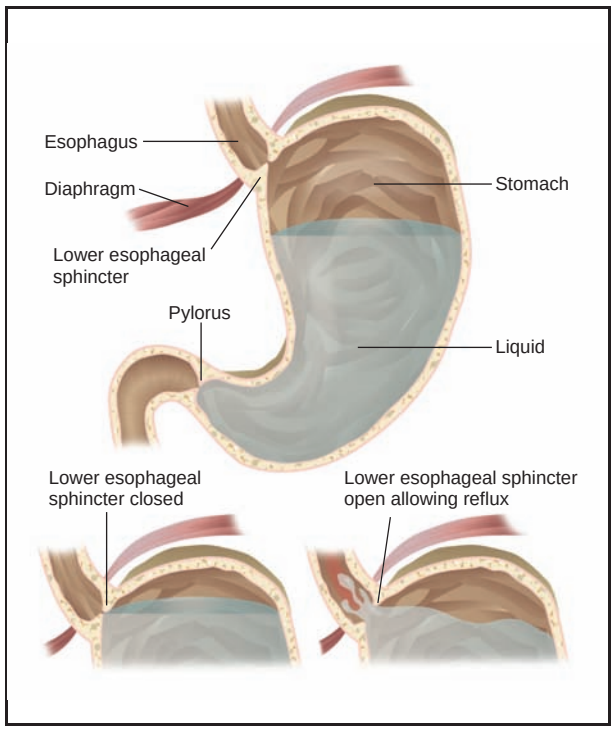
(Table by PreMediaGlobal. Reproduced by permission of Gale, a part of Cengage Learning.)

Description

The mechanism behind GERD is a weakness in the lower esophageal sphincter (LES), causing stomach acids to back into the esophagus. The LES is a muscle located at the bottom of the esophagus that acts as a doorkeeper to the stomach. Normally, when food is eaten, it passes through the esophagus into the stomach, and the LES closes to keep the highly acidic stomach contents from washing back into the esophagus. Although a malfunctioning LES can be present from birth and can cause infants and children to complain of stomachaches and have frequent bouts of **vomiting**, GERD is most often seen in adults.

The esophagus risks being damaged every time stomach acids wash into it. Constant irritation by stomach acids can cause esophagitis, a condition in



Normally, the lower esophageal sphincter keeps the stomach contents contained with the stomach (top). However, with gastroesophageal reflux disease, the sphincter opens, allowing the acidic contents to flow up the esophagus. *(Illustration by PreMediaGlobal. © Cengage Learning®.)*

which the esophagus becomes red and irritated. Because the lining of the esophagus is thinner and less acid-resistant than the stomach or the intestines, untreated GERD over many years can cause **ulcers** to develop in the esophagus. These can bleed and can, in turn, result in anemia. Scar tissue can also build up.

The body may try to protect the esophagus by developing a thick lining made up of cells like those in the stomach and intestine. This is known as Barrett's esophagus and is a pre-cancerous condition that can lead to cancer of the esophagus.

Some people have trouble eating because there is a feeling that something is in their throats or that their food keeps getting stuck when they eat. This may be a serious condition called dysphagia, which develops from long-term GERD. It is a narrowing of the esophagus, caused by a thickening of the lining in response to acids from the stomach. When swallowing hurts, the condition is called odynophagia. This type of GERD often is referred to as silent reflux because no other symptoms are reported.

Everyone experiences heartburn occasionally, especially after overeating or eating fatty foods. Continued heartburn, though, can disrupt sleep. Moreover, if stomach acids keep bathing the esophagus, chronic inflammation of the lower esophagus can occur. In addition, if stomach material from the esophagus finds its way into the windpipe (trachea), it can enter the lungs, leading to **asthma** and **pneumonia**. For elderly individuals who are bedridden, aspiration of stomach contents can cause **choking**, infection, and even suffocation and death.

Causes and symptoms

Causes

Often, a structural abnormality called a **hiatal hernia** is the cause of constant reflux and GERD. In a hiatal **hernia**, a part of the stomach protrudes through a whole in the diaphragm (a sheet of muscle that separates the abdominal cavity from the chest cavity). This condition is more common in older individuals. Impaired motility in the stomach also can be a factor in GERD. In this case, the stomach nerves or muscles do not allow the stomach and the esophagus to contract normally, thereby allowing acid to build up in the esophagus. **Scleroderma**, a disease that causes muscular tissue to thicken, can affect digestive muscles and keep the LES open.

Lifestyle factors affect the development of GERD. Being overweight or pregnant increases abdominal pressure, and can cause the LES to remain open, thus allowing the stomach contents to squeeze into the esophagus. Wearing tight clothing around the abdomen, eating large meals, and lying down after eating can keep the LES open. Some foods may act as triggers for GERD, including chocolate, peppermint, high fat foods, citrus foods, tomato products, and onions. **Smoking** can stimulate acid production in the stomach and also can relax the LES. Consuming alcoholic, caffeinated, and carbonated drinks also can contribute to GERD.

Some medications have been linked to the development of GERD. They include high blood pressure medications such as **calcium channel blockers**, nitrate heart medications, asthma drugs such as theophylline, antidepressants, sedatives such as diazepam (Valium), and corticosteroid drugs. Nitrates in foods also may trigger GERD. Nonsteroidal anti-inflammatory drugs (NSAIDs) such as **aspirin**, ibuprofen, and naproxen can irritate the stomach and lead to GERD.

Symptoms

Although heartburn is the characteristic symptom of GERD, people with this condition also may experience other symptoms. Regurgitation of stomach acid

WWW.BOOKBAZ.IR

into the mouth (sometimes called water brash) is often present. Some individuals report abdominal **pain**, difficulty in swallowing, nausea, morning hoarseness, **sore throat**, coughing, **wheezing**, or a need to repeatedly clear the throat. Others experience vomiting or frequent burping or **hiccups**. A few note weight loss or **snoring**.

Some people do not experience noticeable symptoms. This is or milder forms of common GERD symptoms, but they experienced more instances of difficulty swallowing, vomiting, anemia, and weight loss. The study also found that abdominal pain and heartburn seemed to decrease with age and that GERD in the elderly most often was related to nonsteroidal anti-inflammatory drug (NSAID) use.

Having heartburn several times a week or waking up with heartburn at night is a good indicators that an appointment should be made for evaluation by a physician. If symptoms disturb sleep or interfere with work or leisure activities, a doctor should be consulted. Losing weight, breathing difficulties, vomiting blood, or has producing black, tarry stool, indicate that a doctor should be seen immediately. In addition, if an individual has been treated by a family physician for GERD for more than two years, a consultation with a gastroenterologist (a doctor specializing in diseases of the digestive system) usually is recommended.

Diagnosis

Examination

Because GERD is common, it often will be diagnosed after the doctor takes a thorough medical history, listens carefully for GERD symptoms, and does a **physical examination**. If the patient responds positively to treatment, no further tests are ordered. However, if the patient has serious symptoms such as intense pain, vomiting blood, or rapid weight loss, the doctor will investigate these through a series of tests. In addition, if the patient has been complaining of heartburn for a long time or has been treated for GERD for more than two years, other tests will likely be ordered to gauge the extent of damage done to the esophagus.

Procedures

The most common procedures are the upper gastrointestinal (GI) series and the upper GI **endoscopy**. The upper GI series examines the esophagus, stomach, and the duodenum (the first section of the small intestine). The patient drinks a cup of barium (barium swallow), a metallic, chalky liquid that coats the digestive track and makes it show up on x rays. X rays or images are then taken as the barium flows down the esophagus, into the stomach, and into the duodenum. The patient may be asked to turn to the side so that the technician can gently massage the stomach to move the barium into the duodenum. Images are sent to a video monitor where the doctors and technicians observe the behavior of the upper digestive tract and snap still images from the monitor.

The upper GI series can reveal anatomical changes in the esophagus, such as a hiatal hernia or esophageal narrowing. It also can assess damage to the esophagus, detect stomach ulcers or ulcers in the duodenum, and determine whether an intestinal blockage is present.

The upper GI endoscopy, also called the **esophagogastroduodenoscopy** (EGD), offers a more complete picture of what is happening in the upper digestive tract. It is the test of choice for many gastroenterologists. Before the endoscopy, the patient receives a mild sedative, and then the doctor inserts a small, flexible tube down the patient's throat. At the end of the tube is a light, a tiny camera, and a small instrument used to take tissue samples (biopsies). The camera broadcasts live images from the esophagus and stomach to a video monitor. Using these tools, the doctor can capture still images for further diagnosis and can examine suspicious areas more closely with the camera or by taking tissue samples. The EGD allows the doctor to determine the extent of damage to the esophagus and to rule out serious complications such as Barrett's esophagus. Mild GERD may show no damage to the esophagus at all.

Another test, esophageal manometry, measures pressure within the esophagus and how well the LES functions. A thin tube is inserted through the nose and down the throat. Coupled with the 24-hour pH probe study, esophageal manometry becomes the best determinant of GERD because it monitors how often the patient has reflux into the esophagus during a full day. One episode of acid reflux is considered having a pH of less than 4.0 for at least 15–30 seconds. This test can determine if there is a correlation between episodes of acid reflux and other symptoms, such as chronic **cough**, wheezing, or **sleep apnea**.

To do a pH probe study, a small computer is attached to the outside end of the thin tube in the patient's nose, and the computer is worn around the waist or over the shoulder. The patient goes home, carries on a normal routine, then comes back to have the probe removed and the results analyzed.

A more comfortable form of the 24-hour pH probe study is the Bravo pH probe that is placed in the

esophagus during endoscopy. This tiny probe transmits data to a miniature recorder the size of a paper clip that is worn around the waist. Eventually, the probe makes its way through the digestive system and is passed in the patient's stool in a week to 10 days.

Sometimes, chest x rays are ordered to check for pneumonia or lung damage due to aspiration of stomach contents.

Treatment

The preferred treatments for GERD are lifestyle changes and drugs.

Lifestyle changes

Either prescribed alone or in combination with drug therapy, lifestyle changes can ease many GERD symptoms. Food choices, the timing of meals, and the size of meals are key lifestyle factors. Individuals should avoid foods that trigger GERD and eat smaller, more frequent meals. Doing so helps to control the amount of acid in the stomach. Individuals also should stop eating three hours before lying down. Lying down after eating can cause stomach contents to backflow into the esophagus. In addition, elevating the head of the bed about six inches may help keep acid within the stomach. Losing weight and avoiding slumping will reduce pressure on the stomach.

Drugs

Drugs often are prescribed along with lifestyle changes, even in the early stages of the disease. Commonly, the first medications prescribed are over-the-counter **antacids** and/or histamine-2 receptor blockers (H2 blockers). Antacids, such as Gaviscon, Tums, Maalox, and Mylanta, help neutralize acid already in the stomach or esophagus but do nothing to heal inflammation. Some have a foaming agent that helps prevent acid from backflowing into the esophagus. Unless otherwise instructed by a doctor, antacids can be used every day for three weeks. If taken longer, they can produce **diarrhea**, interfere with **calcium** absorption in the body, and increase levels of magnesium, which can damage the kidneys. Antacids are not recommended for individuals taking drugs to correct **hypothyroidism**.

Common H2 blockers are nizatidine (Axid), ranitidine (Zantac), famotidine (Pecid), and cimetidine (Tagamet). At half the strength of their prescription counterparts, these over-the-counter medications block acid production, but they have no effect on acid already present in the stomach. These drugs should be taken thirty minutes to one hour before meals. H2 blockers do not work as quickly as antacids, but they produce longer relief and are effective in reducing acid reflux at night. These drugs can heal mild esophageal damage but are not strong enough to heal serious injury. Standard dosage for 6–12 weeks has been found to relieve symptoms in half of GERD patients using H2 blockers.

If symptoms do not improve, proton-pump inhibitors (PPIs) may be given. PPIs can be bought without a prescription and, like H2 blockers, are also available in stronger strengths with a prescription. PPIs include esomeprazole (Nexium), omeprazole (Prilosec), lansoprazole (Prevacid), and rabeprazole (Aciphex). These drugs block the production of an enzyme that aids in acid formation. PPIs can reduce stomach acid by more than 95%. They are used to treat GERD and can heal some gastric and duodenal ulcers and prevent upper GI tract bleeding. PPIs are contraindicated for people with **liver disease** and may make the intestinal tract more susceptible to bacterial infections.

In addition to PPIs, the doctor may prescribe coating agents, such as sucralfate (Carfate), to cover the sores and mucous membranes of the esophagus and stomach. This acts as a protective barrier.

Some doctors also a prokinetic agent to tighten the LES and promote faster emptying of the stomach. Metaclopramide (Reglan) is the only prokinetic drug approved for use in the United States. Many doctors are reluctant to use prokinetic drugs because they have serious side effects.

Surgery

If all other treatments fail, surgery is a final option. A surgical procedure called fundoplication creates a one-way valve into the stomach. During surgery, the doctor wraps a part of the stomach around the esophagus and sews it down. This procedure can be done laparoscopically, a less invasive surgical method in which the doctor makes small cuts into the abdomen to insert a camera and the surgical instruments. Laparoscopic surgery produces very little scarring and has a faster recovery rate than traditional open surgery. However, the benefits of fundoplication have been challenged in some studies.

Certain endoscopy treatments can be used to repair the upper digestive tract instead of using surgery. Plication allows the doctor to stitch tears in the esophagus or narrow the LES. The Stretta procedure uses radiofrequency energy to cause the LES sphincter to tighten. The Enteryx procedure lets the doctor inject a bulking material into the LES to narrow

WWW.BOOKBAZ.IR

KEY TERMS

Calcium channel blocker—A drug that lowers blood pressure by regulating calcium-related electrical activity in the heart.

Dysphagia—Difficulty in swallowing, as if something is stuck in the throat.

Esophagogastroduodenoscopy (EGD)—A test that involves visually examining the lining of the esophagus, stomach, and upper duodenum with a flexible fiber-optic endoscope.

Esophagus—The muscular tube that leads from the back of the throat to the stomach. Coated with mucus and surrounded by muscles, it pushes food to the stomach by contraction.

Fundoplication—A surgical procedure that tightens the lower esophageal sphincter by stretching and wrapping the upper part of the stomach around the sphincter.

Gastroenterologist—A physician who specializes in diseases of the digestive system.

H2 Blockers—Medications used to treat some GERD symptoms, for example, Tagamet, Pepcid, Axid.

Heartburn—A burning sensation in the chest that can sometimes also be felt in the neck, throat, and face. It is the primary symptom of GERD.

Hiatal hernia—A condition in which part of the stomach protrudes above the diaphragm next to the esophagus.

Laparoscopic surgery—A minimally invasive surgery in which a camera and surgical instruments are inserted through a small incision.

Lower esophageal sphincter (LES)—A muscular ring at the base of the esophagus that keeps stomach contents from entering back into the esophagus.

Odynophagia—Pain felt when swallowing.

pH—A measure of the acidity of a fluid. On a scale of 1–14, a pH of 7 is neutral. Higher pH readings are alkaline and lower pH readings are acidic.

Silent reflux—An acid reflux problem that does not have marked symptoms but can cause chronic, recurrent respiratory symptoms much like asthma.

Sleep apnea—A sleep disorder in which breathing stop briefly then resumes on its own. These pauses can occur many times each night, resulting in poor quality sleep.

Water brash—The flow of saliva and stomach acid back up the esophagus and into the throat or lungs.

it. As of 2014, these procedures were not widely available but were being used at some larger medical centers.

Alternatives

Alternative remedies include eating bananas or drinking chamomile or ginger tea. Chamomile should be avoided by people who have ragweed **allergies**. Some people eat licorice to balance the acid output in the stomach and to increase the mucous coating of the esophagus, but this is contraindicated for people with high blood pressure. Teas made from marsh mallow root, papaya, fennel, and catnip are also suggested treatments for heartburn, as well as eating papayas.

Homeopathic remedies most recommended are Nux vomica, Carbo vegetabilis, and Srsenicum album. **Acupuncture** and **acupressure** have also been used to treat heartburn.

In addition to the lifestyle changes listed above, a common home remedy offering temporary relief is drinking water with **sodium** bicarbonate (baking soda) in it. However, this remedy can also add uncomfortable gas to the stomach, more sodium to the diet, which can increase blood pressure, and the excessive bicarbonate can produce rebound hyperacidity with worsening symptoms.

Prognosis

In most cases, GERD is easily managed. Between 80% and 90% of individuals improve with drug therapy. However, the length of treatment varies. Some patients may not see improvement for several weeks or months. Some patients can experience relief after two to three months of treatment and are able to modify their lifestyle to minimize symptoms so that medications are reduced or discontinued. Many patients with serious, persistent GERD may need to take medications for the rest of their lives.

Even with successful treatment, some patients experience acid breakthrough. This response occurs when symptoms appear even though the patient has faithfully taken medications. Some patients on PPIs

may be symptom free during the day but wake up at night with heartburn. Sometimes, an H2 blocker is given to the patient at night in addition to PPI medications. Some patients on H2 blockers may benefit from a combination pill that contains an antacid and an H2 blocker.

Untreated GERD can lead to the development of Barrett's esophagus. Barrett's is a pre-cancerous condition. Many times it can be reversed with proper treatment of GERD.

Prevention

Symptoms of GERD can be prevented by taking drugs as prescribed, avoiding alcohol, not smoking, eating smaller meals, limiting fatty foods, and eliminating trigger foods. Individuals should avoid belts and tight clothing around the waist and try to lose excess weight. Individuals may chew gum or suck on hard candies to increase saliva production, which can sooth the esophagus and wash the acid back to the stomach. People with heartburn should wait two hours after eating before exercising and plan not to eat anything at least three hours before lying down. Finally, elevating the head of the bed at least six inches and sleeping on the left side may reduce nighttime heartburn.

Gastrostomy

Definition

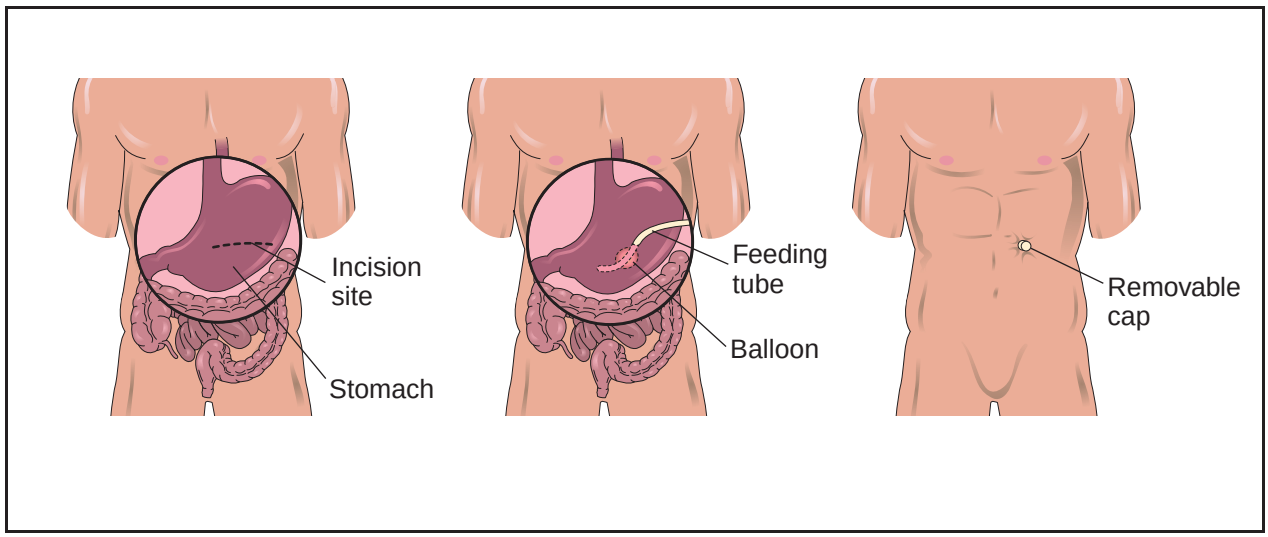
Gastrostomy is a surgical procedure for inserting a tube through the abdomen wall and into the stomach. The tube, called a "g-tube," is used for feeding or drainage.

Purpose

Gastrostomy is performed because a patient temporarily or permanently needs to be fed directly through a tube in the stomach. Reasons for feeding by gastrostomy include **birth defects** of the mouth, esophagus, or stomach, and neuromuscular conditions that cause people to eat very slowly due to the shape of their mouth or a weakness affecting their chewing and swallowing muscles.

Gastrostomy is also performed to provide drainage for the stomach when it is necessary to bypass a longstanding obstruction of the stomach outlet into the small intestine. Obstructions may be caused by peptic ulcer scarring or a tumor.

WWW.BOOKBAZ.IR



Gastrostomy is a procedure in which the surgeon makes an opening into the stomach and inserts a feeding tube for feeding or for drainage. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Demographics

In the United States, gastrostomies are more frequently performed on older individuals.

Description

Gastrostomy, also called gastrostomy tube (g-tube) insertion, is surgery performed to give an external opening into the stomach. Surgery is performed either when the patient is under general **anesthesia** or under local anesthesia.

The procedure is performed at a hospital or surgical clinic by a surgeon or gastroenterologist trained in endoscopy and placement of these tubes.

Fitting the g-tube usually requires a short surgical operation that lasts about 30 minutes. During the surgery, an opening (stoma) about the diameter of a small pencil is cut in the skin and into the stomach; the stomach is then carefully attached to the abdominal wall. The g-tube is then fitted into the stoma. It is a special tube held in place by a disc or a water-filled balloon that has a valve inside allowing food to enter, but nothing to come out. The hole can be made using two different methods. The first uses a tube called an endoscope that has a light at the end, which is inserted into the mouth and fed down the esophagus and into the stomach. The light shines through the skin, showing the surgeon where to perform the incision. The other procedure does not use an endoscope. Instead, a small incision is made on the left side of the abdomen; an incision is then made through the stomach. A small, flexible, hollow tube, usually made of polyvinyl chloride or rubber, is inserted into the stomach. The stomach is stitched tightly around the tube, and the incision is closed.

The length of time the patient needs to remain in the hospital depends on the age of the patient and the patient's general health. In some cases, the hospital stay can be as short as one day, but often is longer. Normally, the stomach and abdomen heal in five to seven days.

The cost of the surgery varies, depending on the age and health of the patient. Younger patients are usually sicker and require more intensive, and thus more expensive, care. The procedure is normally covered by medical insurance.

Preparation

Before the operation, the doctor will perform an **endoscopy** and take x rays of the gastrointestinal tract. Blood and urine tests will also be performed, and the patient will meet with the anesthesiologist to evaluate any special conditions that might affect the administration of anesthesia.

Aftercare

Immediately after the operation, the patient is fed intravenously (through a vein) for at least 24 hours. Once bowel sounds are heard, indicating that the gastrointestinal system is working, the patient can begin clear liquid feedings through the tube. The volume of the feedings is gradually increased.

KEY TERMS

Anesthesia—A combination of drugs administered by a variety of techniques by trained professionals that provide sedation, amnesia, analgesia, and immobility adequate for the accomplishment of a surgical procedure with minimal discomfort, and without injury to the patient.

Endoscopy—A procedure in which an instrument containing a camera is inserted into the gastrointestinal tract so that the doctor can visually inspect the gastrointestinal system.

Patient education concerning use and care of the gastrostomy tube is very important. Patients and their families are taught how to recognize and prevent infection around the tube, how to insert food through the tube, how to handle tube blockage, what to do if the tube pulls out, and what normal activities can be resumed.

Results

The patient is able to eat through the gastrostomy tube, or the stomach can be drained through the tube.

Risks

There are few risks associated with this surgery. The main complications are infection, bleeding, dislodgement of the tube, stomach bloating, nausea, and **diarrhea**.

Gastrostomy is a relatively simple procedure. As with any surgery, however, patients are more likely to experience complications if they are smokers, obese, use alcohol heavily, or use illicit drugs. In addition, some prescription medications may increase risks associated with anesthesia.

Morbidity and mortality rates

The mortality rate of people who have had a gastrostomy is relatively high, but the cause of death is almost always related to the illness or conditions that necessitated the insertion of the tube rather than to the actual surgical procedure.

Alternatives

There are no alternatives to a gastrostomy because the decision to perform it is made when a person is unable to take in enough calories to meet the demands of the body.

Gaucher disease

Definition

Gaucher disease is a rare genetic disorder that results in accumulation of fatty molecules called cerebrosides. It can have serious effects on numerous body organs including the liver, spleen, bones and central nervous system. Treatments based on molecular biology are becoming available, but are very expensive.

WWW.BOOKBAZ.IR

Description

Gaucher disease was first described by the French physician Philippe Gaucher in 1882. It is the most common of a class of diseases called lysosomal storage diseases, each of which is characterized by the accumulation of a specific chemical substance (a different substance depending on the exact disease). Gaucher disease is characterized by a wide array of different symptoms and the severity of the disease ranges from undetectable to lethal.

Three forms of the disease are recognized: Types I, II and III. Type I is by far the most common and shows the mildest symptoms. It is non-neuronopathic, meaning that the nervous system is not attacked. The onset of Type I can occur at any age in childhood or adult life with the average age of onset at about 21 years. Some affected individuals are have no symptoms throughout adult life. Type II, the infantile form, accounts for less than 1% of patients with Gaucher disease. It is neuronopathic (attacks the nervous system); nervous system effects are severe, and victims often die within the first year of life. Type III most often has its onset during childhood and has some of the features of both the adult and infantile forms. This affects less than 5% of persons with Gaucher disease.

Gaucher disease is caused by the absence, or near absence, of activity of an enzyme called glucocerebrosidase (GC). The normal action of GC is to break down a common molecule called glucocerebroside. If not broken down, glucocerebroside accumulates in certain cells to levels that can cause damage, especially in the spleen, liver, and bone. The common link among these organs is that they house a cell type called a macrophage. A macrophage is a large cell that surrounds and consumes a foreign substance (such as bacteria) in the body. The cellular structures in which glucocerebroside accumulates are called lysosomes.

The three forms of Gaucher disease also differ in their population genetics. Type I is most common in persons of eastern European (Ashkenazi) Jewish descent. Among this population, the disease occurs at a rate of one in 450 live births and about one in 10 to 15 persons are carriers, making it the most common genetic disease affecting Jewish people. The other two types are equally frequent in all ethnic groups. Type II occurs at a rate of one in 100,000 live births, while Type III is estimated to occur in one in 50,000 live births.

Causes and symptoms

Lack of the GC enzyme is caused by a mutation in the glucocerebrosidase gene. The gene is located on chromosome 1. There have been more than 100 mutations described in this gene that causes Gaucher disease. Gaucher disease is inherited in an autosomal recessive pattern. This means that two defective gene copies must be inherited, one from each parent, for the disease to manifest itself. Persons with only one gene mutation are carriers for the disorder. A person who is a carrier for Gaucher disease does not have any symptoms and does not know he or she is a carrier unless he or she has had specific testing. When both parents are carriers for Gaucher disease, there is a one in four chance (25%) in each **pregnancy** for a child to have Gaucher disease. There is a two in three chance that a healthy sibling of an affected child is a carrier.

The results of Gaucher disease are widespread in the body and include excessive growth of the liver and spleen (hepatosplenomegaly), weakening of bones, and, in acute cases, severe nervous system damage. Many patients experience "bone crises," which are episodes of extreme **pain** in their bones.

There is a wide array of other problems that occur with Gaucher disease, such as anemia (fewer than normal red blood cells). Just how these other symptoms are caused is not known. Nor is it known why some patients have very mild disease and others have much more significant problems. Even identical twins with the disease can have differing symptoms.

Diagnosis

Diagnosis of Gaucher disease, based initially on the symptoms described above, can be confirmed by microscopic, enzymatic, and molecular tests. Biopsy (surgical removal of tissue from a problem area) of tissue is helpful for microscopic diagnosis. When biopsy tissue is examined under the microscope, cells will appear swollen and will show characteristic features of the cytoplasm (part of the cell body along with the nucleus) and nucleus. Enzyme tests will show deficiency (<30% of normal levels) of the enzyme GC. Molecular analysis of DNA samples looking at four of the more common mutations will show defects in the gene for GC in 95% of Ashkenazi Jewish individuals and in 75% of non-Jewish people. Diagnosis can be performed prenatally (before birth) if the parents' mutations are known using **amniocentesis** or **chorionic villus sampling**.

Diagnosis as to which of the three types of Gaucher disease an individual has is based on the symptoms, rather than on test results.

Treatment

Until the 1990s, only supportive therapy could be offered. **Analgesics** are used to control pain.

Orthopedic treatment is used for bone **fractures**. In some cases, surgical removal of the spleen may be necessary. Several treatments for anemia have been used, including vitamin and iron supplements, blood transfusions, and bone marrow transplants.

The newest form of treatment for Gaucher disease is enzyme replacement therapy, in which GC can be administered intravenously. The enzyme can be prepared either by purification from placentas (alglucerase) or by recombinant DNA manufacturing techniques (imiglucerase). Either way, the cost of treatment ranges from $100,000 to $400,000 per year, which can prevent many from obtaining treatment.

Enzyme replacement is effective at reducing most Gaucher symptoms. The notable exception is neurologic damage in Type II disease, which remains unimproved by this treatment. This treatment is not recommended for individuals who are asymptomatic. The efficacy for the treatment of Type III Gaucher disease is not known. Many questions remain about enzyme replacement therapy in regard to dosage, and method and frequency of administration. The treatment program should be individualized for each patient.

Prognosis

A patient's expected lifespan varies greatly with the type of Gaucher disease. Infants with Type II disease have a life span of one to four years. Patients with Types I and III of the disease have highly variable outcomes with some patients dying in childhood and others living full lives. Little is known about the reasons for this variability.

Prevention

Genetic counseling is advised for individuals with Gaucher disease and for their relatives to accurately assess risk and discuss testing options. For couples who previously had a child with Gaucher or in situations where both parents are carriers for known Gaucher mutations, prenatal diagnosis is available to determine whether a pregnancy is affected. Families in which a person has been diagnosed with Gaucher disease can have DNA testing, which enables other relatives to determine their carrier status. Prospective parents can then use that information to conduct family planning or to prepare for a child who may have special circumstances.

Families in which both parents are known to be a carrier of a mutation for Gaucher disease could consider preimplantation genetic diagnosis. This relatively new procedure can select an embryo without both Gaucher disease mutations prior to implantation of the embryo into the uterus. This technique is only available at selected genetics centers.

Currently, population screening for Gaucher disease is not standard of care.

KEY TERMS

Cerebrosides—Fatty carbohydrates that occur in the brain and nervous system.

Enzymatic replacement therapy—A treatment method used to replace missing enzymes. It is possible to synthesize enzymes and then inject them intravenously into patients.

Glucocerebroside—A cerebroside that contains glucose in the molecule.

Gender dysphoria

Definition

Gender dysphoria was formerly classified as gender identity disorder. Gender identity disorder (GID)

WWW.BOOKBAZ.IR

as defined by the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV*), is a condition characterized by a persistent feeling of discomfort or inappropriateness concerning one's anatomic sex. The disorder typically begins in childhood with gender identity disconnects and is manifested in adolescence or adulthood by a person dressing in clothing associated with the desired gender (cross-dressing), as opposed to one's birth gender, and exhibiting other behaviors associated with the self-perceived sex identity. In extreme cases, persons with gender identity disorder may seek sexual reassignment surgery (SRS), also known as a "sex-change" operation.

In the fifth edition of *DSM* (*DSM-5*) the name of GID was changed to gender dysphoria, eliminating the term "disorder" and dividing the condition into two subgroups on the basis of age. The names for the condition are "Gender dysphoria in children" and "Gender dysphoria in adolescents or adults." The English word *dysphoria* comes from two Greek words meaning "hard" or "difficult" and "to bear" or "to carry," and refers to a chronic or persistent mood of sadness or generalized unease or discomfort. The reader should note that dysphoria is a general term for a condition that can be experienced as a result of **bereavement** or everyday **stress** as well as being a feature of gender issues, depression, and some **anxiety disorders**.

The major changes in *DSM-5* were based on the desire to remove the stigma of mental illness associated with the term "disorder" and to acknowledge the distinction between gender dysphoria related to a disorder of sex development (DSD) and gender dysphoria in a person without a DSD. "Disorder of sexual development" is the preferred term for disorders in which a genetic mutation or hormonal imbalance leads to ambiguous genitalia at birth or other abnormalities of sexual development. The baby's genitalia may appear as normally female, ambiguous, or male but with a very small penis (micropenis). DSDs are sometimes called "intersex conditions."

Demographics

Gender dysphoria is thought to be more prevalent in males than in females. It is estimated that 1 in every 30,000 males and 1 in every 100,000 females in European and North American countries seeks sexual reassignment surgery (SRS). Other researchers note, however, that these figures do not include people who experience a conflict between their biological sex and their perception of themselves as members of the opposite sex but who choose not to seek surgical treatment. Other figures that have been given are 1 in every 10,000 males and 1 in every 30,000 females. Reliable estimates of prevalence for either males or females, however, were not available as of 2014.

Description

Gender dysphoria is a distressing condition to those who have it. It is especially difficult to cope with because it remains unresolved unless and until sexual reassignment surgery has been performed. Most people with this disorder grow up feeling rejected and out of place. **Suicide** attempts and substance **abuse** are common. Most adolescents and adults with the disorder eventually attempt to pass or live as members of the opposite sex.

Gender dysphoria may be as old as humanity. Cultural anthropologists and other scientists have observed a number of cross-gender behaviors in classical and Hindu mythology, Western and Asian classical history, and in many late nineteenth- and early twentieth-century preliterate cultures, including several Native American tribes. This consistent record across cultures and time lends support to the notion that the disorder may be, at least in part, biological in origin. Not all behavioral scientists share this hypothesis, however.

Behavioral experimentation, particularly when a child is young, is considered normal. As they grow, children will often experiment with a variety of gender role behaviors as they learn to make the fine distinctions between masculine and feminine role expectations of the society in which they live. Some young boys occasionally exhibit behaviors that Western culture has traditionally labeled as feminine. Examples of these behaviors include wearing a dress, using cosmetics, or playing with dolls.

In a similar manner, some young girls will occasionally assume masculine roles during play. An example of this behavior includes pretending to be the father when playing house. Some girls temporarily adopt a cluster of masculine behaviors. These youngsters are often designated as tomboys. Most experts agree that such temporary or episodic adopting of behaviors opposite to one's gender is normal and usually constitute learning experiences in the acquisition of normal sex role socialization.

In cases that are considered pathological, however, children deviate from the typical model of exploring masculine and feminine behaviors. Such children develop inflexible, compulsive, persistent,

and rigidly stereotyped patterns. On one extreme are boys who become excessively masculine. The opposite extreme is seen in effeminate boys who reject their masculinity and rigidly insist that they are really girls or that they want to become mothers and bear children.

Boys with these traits frequently avoid playing with other boys, dress in female clothing, play predominantly with girls, try out cosmetics and wigs, and display stereotypically feminine gait, arm movements, and body gestures. Although much less common, some girls may similarly reject traditionally feminine roles and mannerisms in favor of masculine characteristics, including a refusal to urinate sitting down. Professional intervention is required for both extremes of gender role behavior.

Gender dysphoria is different from transvestitism or transvestic fetishism. Transvestic fetishism is classified as a paraphilia or type of sexual behavior in which a person derives sexual excitement from behavior that is unusual, extreme, or criminal. Transvestic fetishism refers to deriving sexual excitement from wearing clothing and accessories associated with the opposite sex in one's particular society, as distinguished from wearing such clothing for a theatrical performance or costume party. It is a paraphilia found primarily in males; there were no cases in the English-language medical literature as of 2014 of women becoming sexually excited by wearing men's clothing. Transvestic fetishism is not necessarily associated with gender identity disorder/dysphoria, as most men who engage in transvestic fetishism are content with their assigned sex.

Adults with gender dysphoria sometimes live their lives as members of the opposite sex. They often cross-dress and prefer to be seen in public as a member of the other sex. Some people with the disorder seek gender reassignment surgery.

Persons with gender dysphoria frequently state that they were born the wrong sex. They may describe their sexual organs as being ugly and may refrain from touching their genitalia. People with gender dysphoria may also try to hide their secondary sex characteristics. For instance, males may try to shave off or pluck their body hair. Many men elect to take estrogens in an effort to enlarge their breasts. Females may try to hide their breasts by binding them. There is a growing movement among people who consider themselves transgendered to demand that the condition not be viewed or classified as a disorder but as part of a spectrum of sexual development.

Causes and symptoms

Causes

There was no consensus as of 2014 regarding the causes of gender dysphoria. Various theories have been proposed, such as:

- childhood sexual abuse or traumatic injury to the genitals
- homosexual orientation
- genetic mutations
- variations in brain structure
- variations in brain function
- prenatal exposure to androgens (male sex hormones), the lack of such exposure, or fetal insensitivity to androgens

The sex of a human baby is determined by chromosomes. Males have a Y chromosome and one X chromosome, while females have two X chromosomes. The Y chromosome carries a gene known as the "testis-determining factor." This gene sets off a developmental pathway that is typically male, resulting in testicular development and development of secondary sexual structures that are male, including a penis and scrotum and differentiation in the fetal brain. Embryos lacking the testis-determining factor usually develop as females. The newly formed testes are responsible for releasing the hormones that continue the fetus on a male developmental pathway.

These prenatal events provide the biological basis for gender dysphoria. Hormone levels must be appropriate for male development during the appropriate developmental windows for typical male development to occur. In addition, the cellular pathways that recognize the signals the hormones send must also be in place. Changes in hormone levels from the norm or exposure to environmental compounds that behave like hormones in the fetus can alter male development, resulting in a feminized fetus if this alteration ends in inhibition of typical male development.

Disruptions of hormone signaling may arise from a variety of sources, including a disorder in the mother's endocrine system, maternal stress, maternal medications, and some environmental endocrine-active substances.

Postmortem studies conducted on male-to-female transsexuals, non-transsexual men, and non-transsexual women show a significant difference in sex-specific brain structures. Studies have shown that in male-to-female transsexuals, for example, brain structures look like those of nontransgendered women. These studies indicate that one's sense of gender resides in the brain

WWW.BOOKBAZ.IR

and that it may be biochemically determined. One hypothesis underlying the link between gonadal sex and the sex of the brain is the organization-activation hypothesis. According to this hypothesis, the hormones that organize the body as masculine (result in the formation of a penis rather than a clitoris) also organize the brain as masculine. At **puberty**, hormones activate the brain for gender-specific sex behavior. In some cases, there may be a disconnect between gonadal development and the brain's sexual development.

In addition to biological factors, such environmental conditions as socialization are thought by some to contribute to gender identity disorder. Social learning theory, for example, proposes that a combination of observational learning and different levels and forms of reinforcement by parents, family, and friends determine a child's sense of gender, which in turn leads to what society considers appropriate or inappropriate behavior. Recent research, however, suggests that even when people who are transgendered or born with ambiguous genitalia are reared based on their assigned sex, they still retain their perceived sexual identity.

Diagnosis

While a patient with gender issues may begin by consulting a family doctor, referral to a mental health professional is needed to make a formal diagnosis of gender identity disorder. In most cases, the professional will be either a psychiatrist or a clinical psychologist. He or she begins by taking a careful personal history of the patient and obtaining the age of the patient, and determines whether the patient's sexual attraction is to males, females, both, or neither. Laboratory tests are neither available nor required to make a diagnosis of gender dysphoria.

Patients and their families may wish to visit clinics that specialize in assessment of gender dysphoria issues.

Examination

It is very important not to overlook a physical illness, such as a tumor that might mimic or contribute to a psychological disorder. If there is any question that a physical problem might be the underlying cause of an apparent gender dysphoria, a mental health professional should recommend a complete **physical examination** by a medical doctor. The patient may be referred to an endocrinologist, a physician who specializes in diagnosing and treating disorders of the glands that produce sex hormones, to determine whether a hormonal imbalance is a factor in the patient's condition.

Tests

Urine and blood samples are taken to rule out previously undiagnosed hormonal disorders. In a few cases, the patient may be given an x ray or other imaging studies to rule out abnormalities of, or injuries to, the brain.

Criteria for gender dysphoria

Diagnosis of a psychiatric disorder or condition according to *DSM* requires the psychiatrist or psychologist to determine whether the patient meets a set of criteria defined by the manual. The criteria requires that:

- The person feels a strong and persistent cross-gender identification.
- The person experiences persistent discomfort with his or her sex or a sense of inappropriateness in the gender role of one's birth sex.
- The disturbance is not concurrent with a physical intersex condition.
- The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

In children with a persistent cross-gender identification, the disturbance is manifested by four (or more) of the following:

- Repeatedly stating a desire to be, or insistence that he or she is, a member of the other sex.
- Strong preference for wearing clothes of the opposite gender. In boys, displaying a preference for cross-dressing or simulating female attire; in girls, insistence on wearing only stereotypically masculine clothing.
- Displaying strong and persistent preferences for cross-sex roles in make-believe play or experiencing persistent fantasies of being a member of the other sex.
- Having an intense desire to participate in the games and pastimes that are stereotypical of the other sex.
- Exhibiting a strong preference for playmates of the other sex.

Among adolescents and adults, the disturbance is manifested by symptoms such as a stated desire to become a member of the other sex, frequent passing as a person of the other sex, a desire to live or be treated as the other sex, or the conviction that he or she has the typical feelings and reactions of the other sex. These characteristics cannot be merely from a

KEY TERMS

Cross-dressing—Wearing clothes and other accessories associated with the opposite sex in one's particular society.

Disorder of sex development (DSD)—The term that is increasingly preferred for an atypical pattern of chromosomal, genital, or gonadal development. It is also known as "disorder of sex differentiation."

Dysphoria—A persistent mood of sadness, discomfort, or general unease. The English word comes from two Greek words meaning "difficult" or "hard" and "to bear."

Eunuch—A castrated male, often one castrated at an early age with noticeable hormonal consequences.

Gender dysphoria—Persistent personal discomfort with one's present gender.

Intersex—A term that is sometimes used to refer to having a sexual anatomy that is not standard for either a male or a female. It covers a number of different conditions but is considered a convenient umbrella term for discussing disorders of sex development.

Paraphilia—A type of sexual behavior in which a person derives sexual excitement from behavior that is unusual, extreme, or criminal.

Stigma—Any personal attribute that causes a person to be socially shamed, avoided, or discredited. Mental disorders are a common cause of stigma.

Transvestic fetishism—A condition in which a person is sexually aroused by wearing the clothing of the other sex (as distinct from cross-dressing for a theater role or costume party).

desire for any perceived cultural advantages of being the other sex.

Among children that feel a discomfort regarding his or her gender, the disturbance is manifested by any of the following:

- Among boys, asserting that his penis or testes are disgusting or will disappear, asserting that it would be better not to have a penis, or having an aversion toward rough-and-tumble play and rejecting male stereotypical toys, games, and activities.
- Among girls, rejecting the gender-typical practice of urinating in a sitting position, asserting that she has or will grow a penis, or stating that she does not want to grow breasts or menstruate, or having a marked aversion toward normative feminine clothing.

Among adolescents and adults, the disturbance is manifested by symptoms such as preoccupation with getting rid of primary and secondary sex characteristics (e.g., request for hormones, surgery, or other procedures to alter sexual characteristics to simulate the other sex) or a belief that he or she was born the wrong sex.

DSM-5 criteria for gender dysphoria

IN CHILDREN. There are two subtypes specified of gender dysphoria in children: a) with a disorder of sex development; and b) without a disorder of sex development.

- Criterion A: A marked incongruence between one's experienced/expressed gender and assigned gender, of at least six months duration, as manifested by at least six of the following indicators, including the first: 1) a strong desire to be of the other gender or an insistence that he or she is the other gender (or some alternative gender different from one's assigned gender); 2) in boys, a strong preference for cross-dressing or simulating female attire; in girls, a strong preference for wearing only typical masculine clothing and a strong resistance to the wearing of typical feminine clothing; 3) a strong preference for cross-gender roles in make-believe or fantasy play; 4) a strong preference for the toys, games, or activities typical of the other gender; 5) a strong preference for playmates of the other gender; 6) in boys, a strong rejection of typically masculine toys, games, and activities and a strong avoidance of rough-and-tumble play; in girls, a strong rejection of typically feminine toys, games, and activities; 7) a strong dislike of one's sexual anatomy; 8) a strong desire for the primary and/or secondary sex characteristics that match one's experienced gender
- Criterion B: the condition is associated with clinically significant distress or impairment in social, occupational, or other important areas of functioning, or with a significantly increased risk of suffering, such as distress or disability.

IN ADOLESCENTS AND ADULTS. As with children, *DSM-5* specifies two subtypes of gender dysphoria in adolescents and adults: with or without a disorder of sex development.

- Criterion A: A marked incongruence between one's experienced/expressed gender and assigned gender, of at least six months duration, as manifested by two

WWW.BOOKBAZ.IR

or more of the following indicators: 1) a marked incongruence between one's experienced/expressed gender and primary and/or secondary sex characteristics (or, in young adolescents, the anticipated secondary sex characteristics); 2) a strong desire to be rid of one's primary and/or secondary sex characteristics because of a marked incongruence with one's experienced/expressed gender (or, in young adolescents, a desire to prevent the development of the anticipated secondary sex characteristics); 3) a strong desire for the primary and/or secondary sex characteristics of the other gender; 4) a strong desire to be of the other gender (or some alternative gender different from one's assigned gender); 5) a strong desire to be treated as the other gender (or some alternative gender different from one's assigned gender); 6) a strong conviction that one has the typical feelings and reactions of the other gender (or some alternative gender different from one's assigned gender).

- Criterion B: same as Criterion B for children.

MALE-TO-EUNUCH GENDER DYSPHORIA. Some researchers suggested that *DSM-5* add a new category of gender dysphoria known as male-to-eunuch gender dysphoria. This category would have included males who do not identify with either their birth sex or with a female gender identity. They seek castration as a way to align their bodies with their brain sex. It was estimated that there were between 7,000 and 10,000 voluntary eunuchs in Canada and the United States in 2011. *DSM-5* has not incorporated male-to-eunuch gender identity disorder.

Treatment

Psychotherapy

One common form of treatment for gender dysphoria is **psychotherapy**. The initial aim of treatment is to help individuals function in their biologic sex roles to the greatest degree possible. The World Professional Association for Transgender Health, which has formulated and published its own *Standards of Care* manual for working with transgendered people, does not support psychotherapy designed to convert a transgendered person from their own personal perception of their sex.

Sexual reassignment

Adults who have had severe gender dysphoria for many years sometimes request reassignment of their sex, or sex-change surgery. Before undertaking such surgery, they usually undergo hormone therapy to suppress same-sex characteristics and to accentuate other-sex characteristics. For instance, the female hormone estrogen is given to males to make breasts grow, reduce facial hair, and widen hips. The male hormone testosterone is administered to females to suppress menstruation, deepen the voice, and increase body hair. Following the hormone treatments, preoperative candidates are usually required to live in the cross-gender role for at least a year before surgery is performed. This period is known as "real-life experience" or RLE.

Adults seeking sexual reassignment should be screened for medical conditions that can be worsened by cross-sex hormone therapy. These conditions include **heart disease**, **breast cancer**, **liver disease**, migraine headaches, and blood disorders. There are two goals of hormone therapy in adult transsexuals: reduce the secondary sex characteristics of the patient's biological sex; and supply the individual with the hormones of the desired sex. Adults should also be counseled about the possibility of permanent **infertility** if they choose to proceed with sex reassignment. In addition, males seeking reassignment as women should be warned that hormone treatment is likely to lower their sex drive, while women seeking reassignment as men are likely to find their sex drive increased by hormone therapy. In terms of cost, hormone therapy costs between $25 and $200 per month.

Transsexuals in any country must also attend to a number of legal concerns, ranging from changing their name and sex on documents ranging from birth certificates (permitted in some states in the United States) and Social Security registration to driver's licenses, bank accounts, passports, voter registration forms, and the like.

Prognosis

If gender dysphoria in a child persists into adolescence, it tends to be chronic in nature. There may be periods of remission. However, adoption of characteristics and activities typical for one's birth sex is unlikely to occur.

Most individuals with gender dysphoria require and appreciate support from several sources. Families, as well as the person with the disorder, need and appreciate both information and support. Local and national support groups and informational services exist, and healthcare providers and mental health professionals can provide referrals.

There is some disagreement regarding the post-treatment satisfaction of people who have undergone

sexual reassignment surgery. Early surveys indicated that only 1% regretted their transition; however, other surveys have reported that between 8% and 14% regret their change, and that a few persons have re-transitioned to their original gender. In terms of adjustment after SRS, heterosexual transsexuals have poorer outcomes than homosexual transsexuals; older persons and effeminate homosexuals have poorer outcomes; and male-to-female transsexuals have poorer outcomes than female-to-male. In general, satisfactory results are reported in 87% of male-to-female and 97% of female-to-male SRS patients.

Prevention

There is no known way to prevent gender identity disorder/dysphoria because there are several possible causes of the condition that are not completely understood.

Gender issues in mental health

Defining gender

In the social sciences, the concept of gender means much more than biological sex. It refers to socially constructed expectations regarding the ways in which people should think and behave, depending on their

WWW.BOOKBAZ.IR

sexual classification. These stereotypical expectations are commonly referred to as "gender roles." Attitudes toward gender roles are thought to result from complex interactions among societal, cultural, familial, religious, ethnic, and political influences.

Gender affects many aspects of life, including access to resources, methods of coping with **stress**, styles of interacting with others, self-evaluation, spirituality, and expectations of others. These are all factors that can influence mental health either positively or negatively. Psychological gender studies seek to better understand the relationship between gender and mental health in order to reduce risk factors and improve treatment methods.

Traditional gender roles in many Western societies identify masculinity as having power and being in control in emotional situations, in the workplace, and in sexual relationships. Acceptable male behaviors in this traditional construct include competitiveness, independence, assertiveness, ambition, confidence, toughness, anger, and even violence (to varying degrees). Men are expected to avoid characteristics considered feminine, such as emotional expressiveness, vulnerability (weakness, helplessness, insecurity, worry), and intimacy (especially showing affection to other males).

Traditional femininity is defined as being nurturing, supportive, and assigning high priority to one's relationships. Women are expected to be emotionally expressive, dependent, passive, cooperative, warm, and accepting of subordinate status in marriage and employment. Competitiveness, assertiveness, anger, and violence are viewed as unfeminine and are not generally tolerated as acceptable female behavior, although competitiveness is becoming more widely accepted as appropriate for female athletes and political leaders.

Theories of gender

Differences in gender roles have existed throughout history. Evolutionary theorists attribute these differences to the physiological characteristics of men and women that prescribed their best function for survival of the species. In primitive societies, men adopted the roles of hunting and protecting their families because of their physical strength. Women's ability to bear and nurse children led them to adopt the roles of nurturing young, as well as the less physically dependent roles of gathering and preparing food. These gender-dependent labor roles continued into the period of written human history, when people began to live in cities and form the earliest civilized societies.

In the nineteenth century, the industrial movement marked a prominent division of labor into public and private domains. Men began leaving home to work, whereas women worked within the home. Previously, both men and women frequently engaged in comparably respected, productive activities on their homestead. When men began working in the public domain, they acquired money, which was transferable for goods or services. Women's work, on the other hand, was not transferable. Men's relative economic independence contributed to their power and influence, while women were reduced to an image of frailty and emotionality deemed appropriate only for domestic tasks and child rearing.

Sigmund Freud's psychoanalytic theory of human development, which emerged from Freud's late nineteenth-century European setting and medical training, reflected an attitude of male superiority. Freud asserted that as children, boys recognize they are superior to girls when they discover the difference in their genitals, and that girls, on the other hand, equate their lack of a penis with inferiority. According to Freud, this feeling of inferiority causes girls to idolize and desire their fathers, resulting in passivity, masochistic tendencies, jealousy, and vanity, all seen by Freud as feminine characteristics.

Other developmental theorists rejected Freud's notions. Eric Erikson (in 1950) and Lawrence Kohlberg (in 1969) theorized that all humans begin as dependent on caregivers and gradually mature into independent and autonomous beings. Such theories, however, still favored men because independence has historically been considered a masculine trait. By such a standard, men would consistently achieve greater levels of maturity than females.

Nancy Chodorow's object-relations theory (in 1978) favored neither sex. She proposed that children develop according to interactions with their primary caregivers, who tend to be mothers. Mothers, according to her theory, identify with girls to a greater extent, fostering an ability to form rich interpersonal relationships, as well as dependency traits. Mothers push boys toward independence, helping them to adjust to the male-dominated work environment but rendering them unaccustomed to emotional connection. Chodorow's theory suggests both strengths and weaknesses inherent in male and female development, with neither deemed superior.

Around that same time (1974), Sandra Bem advocated for androgyny, or high levels of both

masculinity and femininity, as the key to mental health. Bem constructed the Bem Sex Role Inventory (BSRI), a 60-item questionnaire that measures 20 feminine, 20 masculine, and 20 neutral traits. It classifies subjects as masculine, feminine, androgynous, or undifferentiated. Bem maintains that gender roles are primarily cognitive; that is, that people spontaneously sort attitudes and behaviors into masculine and feminine categories according to the models their culture provides. Sex-typed individuals score highly on the dimension corresponding to their gender while rejecting the characteristics of the other gender. Androgynous individuals score high on both masculine and feminine traits, and typically use situational examples to explain their behavior. Bem concluded that androgyny is a particular way of processing information and that individuals who are androgynous are those who do not use sex-role related cognitive frameworks to guide their information processing.

In the 1980s, such psychologists as Carol Gilligan sought to build respect for stereotypically feminine traits. They introduced the notion that women function according to an ethic of care and relatedness that is not inferior to men's, just different. In 1985, Daniel Stern's developmental theory favored traditional femininity, suggesting that humans start out as unconnected to others and gradually form more complex interpersonal connections as they mature.

The process of learning gender roles is known as "socialization." Children learn which behaviors are acceptable or not acceptable for their sex by observing other people. They may also be shamed by caregivers or peers when they violate gender-role expectations. As a result, gender roles usually become an internal guide for behavior early in childhood. Current studies focus on the ways in which extreme notions of masculinity or femininity affect mental health, and the social processes that shape one's concept of maleness or femaleness.

Psychological and behavioral androgyny are less of a problem in North America and Europe because of widespread changes in society, particularly the entrance of women in large numbers into the military, politics, law, medicine, the ministry, and other occupations that were partly or completely closed to them before World War II. Another factor that has influenced social attitudes toward androgyny is androgynous parenting, a trend in childrearing in which a child's mother and father share equally and relatively interchangeably in parenting responsibilities.

In terms of choices made after adolescence, most young people whose career interests or lifestyle preferences fall outside stereotypical gender roles may more easily find welcoming and supportive communities than they might have before the 1960s. There is also some evidence that older adults with androgynous gender roles enjoy better health and satisfaction with their lives than those who adhere to traditional gender roles. On the other hand, people who grow up within families that recently emigrated from countries still marked by rigid gender roles and stereotypes may find the greater acceptance of androgyny in the West disorienting and upsetting.

Gender-role conflict

According to some researchers, the concepts of masculinity and femininity may simply be sets of personality traits that can be exhibited by either sex, and there may be no true gender differences, although this conclusion is controversial. Individuals vary in degree of adherence to gender roles, resulting in large amounts of behavioral variation within the sexes and potentially less variation between them. However, some scholars maintain that there are specific gender-related traits, including gender bias in mental illness.

Although attitudes toward gender roles are now much more flexible, different cultures retain varying degrees of expectations regarding male and female behavior. Individuals may personally disregard gender expectations, but society may disapprove of their behavior and impose external social consequences. On the other hand, individuals may feel internal shame if they experience emotions or desires characteristic of the opposite sex. In some cultures in which a person's social role is emphasized over individualism, the failure to fulfill that role in ways considered traditionally appropriate can lead to feelings of shame as well. Gender-role conflict, or gender-role stress, results when people feel a discrepancy between how they believe they should act based on gender-role expectations learned in childhood, and how they actually think, feel, or behave. If these discrepancies are unresolved, gender-role conflict contributes to poor mental health.

Gender-role complications

A person's attitude toward the roles associated with his or her gender can be complicated by a number of factors, ranging from having a nonstandard sexual anatomy to bisexual or homosexual

WWW.BOOKBAZ.IR

orientation to unhappiness with one's biological sex (gender dysphoria).

Sexual orientation

Gay men, lesbians, and bisexuals can experience gender-role conflict as well as heterosexual people. Some studies of gay men indicate that effeminate gays are stigmatized inside as well as outside the gay community, and that they have a higher level of mental health problems than gay men who conform more closely to male gender norms. In addition, same-sex partnerships are complicated by the same gender stereotypes that cause stress in male/female relationships. While research does not support the commonplace belief that gay or lesbian couples organize their relationships around traditional gender roles, with one partner being the "butch" (the "man") and the other being the "femme" (the "woman"), such couples are still often troubled by power struggles and domestic violence. In addition to internal conflict about gender roles, bisexuals suffer the additional complication of being distrusted by both homosexual and heterosexual partners; homosexual support groups may reject them if they reveal their heterosexual side; heterosexuals may reject them if they reveal their homosexual feelings.

Disorders of sexual development

Disorders of sexual development (DSDs) is an umbrella term for a group of conditions in which a person has a congenital (present at birth) abnormality or atypical combination of features that make it difficult to determine sex. The abnormalities may be chromosomal, genital, or gonadal. It is estimated that about 1–1.7% of human infants are born with some degree of sexual ambiguity and that between 0.1% and 0.2% are sexually ambiguous enough to require the attention of a medical specialist. Some doctors prefer the term *intersex* to DSD.

In general, parents are more likely to be concerned about a child with ambiguous genitalia than about other intersex conditions that may not be apparent at birth. The most important consideration is to determine the cause of the ambiguous genitalia. The usual tests that are performed include a karyogram to determine the child's karyotype; this diagram of the chromosomes in a cell is usually made from a white blood cell. Other tests include blood and urine samples to evaluate the levels of sex hormones in the blood, and x-ray or **ultrasound** studies to clarify the structure of the child's internal sex organs.

The nest step is gender assignment. The doctor may suggest the gender, depending on the baby's genetic sex, the anatomy of the internal sex organs, and the possibility of future reproduction. Depending on the cause of the DSD, treatment may include hormone therapy or surgery. The therapy plan should always include psychological counseling for both the child and the parents, particularly because the child may wish to identify with the other sex when he or she is older.

Gender-free childrearing

One recent complication in gender issues related to mental health is whether it is either possible or desirable to raise a child without an assigned gender identity. This question was discussed intensively in the spring of 2011 when a couple in Canada made headlines with their announcement that they were keeping their third child's sex a secret from everyone except their two older children. The baby's name, Storm, was deliberately chosen to be gender-neutral. Child psychologists are divided on whether the parents' decision is likely to create problems for Storm as she or he grows older. The same division among experts surfaced in 2009 when a Swedish couple had a child they named Pop; they told a Swedish newspaper that "the decision [to give the baby a gender-free name] stemmed from a feminist philosophy that gender is a social construction." It will take a number of years to evaluate whether these experiments in gender-free childrearing are successful, and if so, what defines their "success."

Gender dysphoria

"Gender dysphoria" is the new name for **gender identity disorder** (GID) as defined by the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV*). Gender dysphoria is a condition characterized by a persistent feeling of discomfort or inappropriateness concerning one's anatomic sex. The disorder typically begins in childhood with rejection of or discomfort with one's birth gender and is manifested in adolescence or adulthood by a person dressing in clothing associated with the desired gender (cross-dressing) and exhibiting other behaviors associated with the self-perceived sex identity. In extreme cases, persons with gender identity disorder may seek sexual reassignment surgery (SRS), also known as a "sex-change" operation.

In the fifth edition of the *DSM* (*DSM-5*) the name of GID has been changed to "Gender Dysphoria," thus eliminating the term "disorder," and dividing the condition into two subgroups on the basis of age. The subgroups are "Gender dysphoria in children" and "Gender dysphoria in adolescents or adults." The

English word *dysphoria* comes from two Greek words meaning "hard" or "difficult" and "to bear" or "to carry," and refers to a chronic or persistent mood of sadness or generalized unease or discomfort. Most people with this disorder grow up feeling rejected and out of place. **Suicide** attempts and substance **abuse** are common. Most adolescents and adults with the disorder eventually attempt to "pass" or live as members of the opposite sex.

Women's issues

Typical stressors

Women are often expected to occupy a number of roles at the same time: wife, mother, homemaker, employee, or caregiver to an elderly parent. Meeting the demands of so many roles simultaneously leads to stressful situations in which choices must be prioritized. Women often must choose whether to pursue or further a career versus whether to devote more time to home and family.

Many women prefer to work outside the home because it gives them a greater sense of life satisfaction. For other women, such as those who run single-parent households, employment is not an option—it is a necessity. Compared with men, women frequently have jobs with less autonomy or creativity, which decreases their level of job satisfaction. Women may also have more difficulty being accepted in the workplace because of hierarchical structures preferring men. Documentation repeatedly shows that women's salaries are lower than those of men in comparable positions; women tend to be paid less even when performing the same jobs as men.

When women do choose or are required to work outside the home, they continue to perform the bulk of household duties as well. Sarah Rosenfield reported that, compared to men, women perform 66% more of the domestic work, sleep a half hour less per night, and perform an extra month of work each year. Needless to say, increased workloads and decreased attention to rest and relaxation are stressful and pose obstacles to women's mental health.

Divorce results in more severe consequences for women who choose or are able to stay home in deference to child rearing. Such women depend on marriage for financial security. Such domestic skills as child care and housecleaning are not highly valued by society and thus are poorly compensated in terms of money. Women who have never been employed and then experience divorce often have few options for securing adequate income.

Although women's ability to form meaningful relationships is a buffer against stress, it can also be a source of stress. Caring about another person can be stressful when that person is not doing well physically or emotionally. Many families take for granted that the female members care for sick children or for elderly parents who are no longer self-sufficient. As a result, many women in their forties or fifties are caught between the needs of their college-age offspring and the needs of dependent parents or in-laws. Interpersonal conflicts resulting from these heavy burdens may cause stress or lower self-esteem; a Canadian study reported in 2011 that women caregivers are still more likely to suffer depression or post-traumatic stress than men placed in a caregiver role. Women may also view unsuccessful relationships as representing failure on their part to fulfill such traditional feminine qualities as nurturance, warmth, and empathy.

Additional sources of stress common to women include victimization, assertiveness, and physical unattractiveness. Victimization is a constant concern due to the power differential between men and women. Assertiveness may be stressful for women who have had little experience in competitive situations. Physical unattractiveness may cause some women who adhere to unrealistic standards of feminine beauty to experience shame. Women considered unattractive may also experience discrimination in the workplace or in admission to higher education. In addition, the double standard of **aging** in contemporary society means that all women will eventually have to cope with the stigma of the putative unattractiveness associated with aging.

Typical coping strategies

Studies suggest that women typically react to stress by seeking social support, expressing feelings, or using distraction. These strategies might include praying, worrying, venting, getting advice, or engaging in behaviors that are not related to the problem at all (including such antisocial behaviors as drinking alcohol). Seeking social support and distraction are considered avoidant coping strategies because they do not focus on solving or overcoming a problem, only on alleviating the stress associated with the problem. Research is inconclusive regarding whether men or women are more likely to use problem solving, which is considered an active coping strategy.

Typical patterns of psychopathology

Women are more likely than men to experience internalizing disorders. Primary symptoms of internalizing disorders involve negative inner emotions as opposed to outward negative behavior. Depression

WWW.BOOKBAZ.IR

(both mild and severe) and **anxiety** (generalized or free-floating anxiety, **phobias**, and panic attacks) are internalizing disorders common to women. Symptoms include sadness; a sense of loss, helplessness, or hopelessness; doubt about one's ability to handle problems; high levels of worry or nervousness; poor self-esteem; guilt, self-reproach, and self-blame; decreased energy, motivation, interest in life, or concentration; and problems with sleep or appetite. Women also are more likely than men to have **eating disorders**, and although incidence of **bipolar disorder** is similar between men and women, women manifest rapid cycling more often and have longer depressive episodes.

Men's issues

Typical stressors

Situations that typically produce stress for men are those that challenge their self-identity and cause them to feel inadequate. If their identity closely matches a traditional male role, they will experience stress in situations requiring subordination to women or emotional expressiveness. They will also experience stress if they feel they are not meeting expectations for superior physical strength, intellect, or sexual performance. Research indicates that men who strictly adhere to extreme gender roles are at higher risk for mental disorders. They are also at greater risk of dying from undiagnosed cancer, **heart disease**, and other physical disorders due to reluctance to consult a doctor when symptoms first appear.

Certain cultures are thought to adhere more strictly to traditional male gender roles. In a study by Jose Abreu and colleagues, Latin American men were identified as adopting the most exaggerated form of masculinity, followed by European Americans, and then African Americans. The Latino image of masculinity is often referred to as *machismo* and includes such qualities as concern for personal honor, virility, physical strength, heavy drinking, toughness, aggression, risk taking, authoritarianism, and self-centeredness. African American males are also thought to have a unique image of masculinity; however, Abreu's study showed that African Americans are more egalitarian in terms of gender roles than European Americans.

Typical coping strategies

Men may respond to stress by putting on a tough image, keeping their feelings inside, releasing stress through such activities as sports, actively attempting to solve the problem, denying the problem, abusing drugs or alcohol, or otherwise attempting to control the problem. As stated previously, research is inconclusive regarding whether males or females use problem-solving strategies more often. This type of coping strategy, however, has more frequently been attributed to males. Problem solving is seen as an active coping strategy, which is more effective than such avoidant strategies as denial, abuse of drugs or alcohol, or refusal to talk about problems.

Typical patterns of psychopathology

Men are more likely than women to experience externalizing disorders. Externalizing disorders are characterized by symptoms involving negative outward behavior as opposed to internal negative emotions. Such externalizing disorders as substance abuse (both drugs and alcohol) and antisocial behavior (such as anger, hostility, aggression, violence, or stealing) are common to men. Substance abuse results in such negative physical and social consequences as **hallucinations**, blackouts, physical dependency, job loss, divorce, arrest, organ and brain damage, and financial debt. Antisocial behavior impairs interpersonal relationships and can also result in negative consequences in other areas of life, such as run-ins with the criminal justice system.

Men are not exempt from such internalizing disorders as anxiety and depression. In fact, one study found that high levels of masculinity appear to be related to depression in males. Some researchers feel that men's abuse of substances could be considered the male version of depression. Because male gender roles discourage admitting vulnerability, men may resort to substance abuse as a way of covering their feelings.

Men who adhere to rigid gender roles are also at a disadvantage in interpersonal relationships, especially intimate relationships. They may avoid emotional expressiveness or may behave in domineering and hostile ways. These behaviors increase their risk of social **isolation**, disconnection from nurturance, and participation in unhealthy relationships.

Mental health

Research indicates that, overall, neither men nor women are at greater risk for developing mental disorders as such. Being male or female may indicate susceptibility to certain types of disorders, however. Neither masculinity nor femininity is uniformly positive; both gender identifications have strengths and weaknesses. For example, femininity appears to be protective against antisocial behaviors and substance

KEY TERMS

Androgyny—The condition of having the characteristics of both a man and a woman, or not being clearly identified as male or female. The English word is a combination of two Greek words meaning "(adult) man" and "woman." Androgyny may refer to a person's physical characteristics, to psychological characteristics, or to behavior.

Bem Sex Role Inventory (BSRI)—A 60-item self-administered test that researchers often use to measure psychological androgyny in test subjects. It was devised in 1971 by Sandra Bem.

Congenital—Present at birth.

Disorder of sex development (DSD)—The term that is increasingly preferred for an atypical pattern of chromosomal, genital, or gonadal development. It is also known as disorder of sex differentiation.

Externalizing disorders—Disorders in which a person acts out inner turmoil or conflict on the external environment. The three major characteristics of externalizing disorders are disruptive, hyperactive, and aggressive behaviors.

Gender dysphoria—Persistent personal discomfort with one's present biological sex.

Genitals—The reproductive organs in either sex, especially the external reproductive organs.

Gonad—The organ that makes gametes (germ cells). The gonads in males are called "testicles" and produce sperm; those in females are called "ovaries" and produce eggs.

Internalizing disorders—Disorders related to issues within the self; depression and the anxiety disorders are two common types of internalizing disorders.

Intersex—A term that is sometimes used to refer to having a sexual anatomy that is not standard for either a male or a female. It covers a number of different conditions but is considered a convenient umbrella term for discussing disorders of sex development.

Karyotype—The number and appearance of a complete set of chromosomes in a species or an individual organism. The arrangement of microphotographs of the chromosomes in a standard photographic format is called a "karyogram."

Socialization—The process through which a person learns his or her roles in society. It includes the society's customs, traditions, and professional roles as well as gender roles.

abuse but is associated with high levels of avoidant coping strategies and low levels of achievement. Masculinity appears to be protective against depression but is high in antisocial behavior and substance abuse.

Information about gender roles has implications for treatment. Women might not seek treatment because of a lack of such resources as money, transportation, or time away from child-care duties. A treatment center that is sensitive to women's issues should seek to provide these resources in order to facilitate access to treatment. Men, on the other hand, might not seek treatment because it is incongruent with their image of masculinity. Therapists may need to offer men less threatening forms of treatment, such as those that focus on cognitive problem solving rather than on emotions.

The focus of therapy may differ according to one's gender issues. Therapists should recognize the potential for shame and defensiveness when exploring gender norms. Externalizing behaviors may point to underlying hidden shame. For women, the importance placed on various roles in their lives and how closely those roles are tied to their self-identity is relevant. Men may be encouraged to connect to the spiritual aspects of their being and to consider less stringent views of masculinity. Therapists should also consider the associated influences of generation, culture, class, occupation, and educational level when exploring gender-role issues. Men often are entering therapy under duress, as the result of a court order or a spousal ultimatum and may begin the therapeutic process from a perspective of defensiveness. In addition, men's reluctance to discuss their emotions means that less is known about their responses to mental health crises than is known about women's responses. A number of researchers maintain that further study of men's experience of mental distress is needed.

Taking either masculine or feminine qualities to an extreme and to the exclusion of the other appears to be detrimental. A non-traditional gender-role orientation would combine the best of both genders: a social focus (reciprocally supportive relationships and a balance between interests of self and others) and active coping strategies.

WWW.BOOKBAZ.IR

Flexibility in using coping strategies is also important. Active, problem-focused coping strategies help to change the situation that is causing the problem. Avoidant or emotion-focused coping strategies manage or reduce emotional distress. Avoidant and emotion-focused strategies may be helpful for the immediate crisis but should be used in combination with more active strategies for complete problem resolution.

Gene therapy

Gene therapy is a rapidly growing field of medicine in which genes are introduced into the body to treat diseases. Genes control heredity and provide the basic biological code for determining a cell's specific functions. Gene therapy seeks to provide genes that correct or supplant the disease-controlling functions of cells that are not, in essence, doing their job. Somatic gene therapy introduces therapeutic genes at the tissue or cellular level to treat a specific individual. Germ-line gene therapy inserts genes into reproductive cells or possibly into embryos to correct genetic defects that could be passed on to future generations. Initially conceived as an approach for treating inherited diseases, like **cystic fibrosis** and Huntington's disease, the scope of potential gene therapies has grown to include treatments for cancers, arthritis, and infectious diseases. Although gene therapy testing in humans has advanced rapidly, many questions surround its use. For example, some scientists are concerned that the therapeutic genes themselves may cause disease. Others fear that germline gene therapy may be used to control human development in ways not connected with disease, like intelligence or appearance.

The biological basis of gene therapy

Gene therapy has grown out of the science of genetics or how heredity works. Scientists know that

WWW.BOOKBAZ.IR

life begins in a cell, the basic building block of all multicellular organisms. Humans, for instance, are made up of trillions of cells, each performing a specific function. Within the cell's nucleus (the center part of a cell that regulates its chemical functions) are pairs of chromosomes. These threadlike structures are made up of a single molecule of DNA (deoxyribonucleic acid), which carries the blueprint of life in the form of codes, or genes, that determine inherited characteristics.

A DNA molecule looks like two ladders with one of the sides taken off both and then twisted around each other. The rungs of these ladders meet (resulting in a spiral staircase-like structure) and are called base pairs. Base pairs are made up of nitrogen molecules and arranged in specific sequences. Millions of these base pairs, or sequences, can make up a single gene, specifically defined as a segment of the chromosome and DNA that contains certain hereditary information. The gene, or combination of genes formed by these base pairs ultimately direct an organism's growth and characteristics through the production of certain chemicals, primarily proteins, which carry out most of the body's chemical functions and biological reactions.

Scientists have long known that alterations in genes present within cells can cause inherited diseases like cystic fibrosis, sickle-cell anemia, and **hemophilia**. Similarly, errors in the total number of chromosomes can cause conditions such as **Down syndrome** or **Turner syndrome**. As the study of genetics advanced, however, scientists learned that an altered genetic sequence can also make people more susceptible to diseases, like atherosclerosis, cancer, and even **schizophrenia**. These diseases have a genetic component, but are also influenced by environmental factors (such as diet and lifestyle). The objective of gene therapy is to treat diseases by introducing functional genes into the body to alter the cells involved in the disease process by either replacing missing genes or providing copies of functioning genes to replace nonfunctioning ones. The inserted genes can be naturally occurring genes that produce the desired effect or may be genetically engineered (or altered) genes.

Scientists have known how to manipulate a gene's structure in the laboratory since the early 1970s through a process called gene splicing. The process involves removing a fragment of DNA containing the specific genetic sequence desired then inserting it into the DNA of another gene. The resultant product is called recombinant DNA and the process is genetic engineering.

There are basically two types of gene therapy. Germline gene therapy introduces genes into reproductive cells (sperm and eggs) or someday possibly into embryos in hopes of correcting genetic abnormalities that could be passed on to future generations. Most of the current work in applying gene therapy, however, has been in the realm of somatic gene therapy. In this type of gene therapy, therapeutic genes are inserted into tissue or cells to produce a naturally occurring protein or substance that is lacking or not functioning correctly in an individual patient.

Viral vectors

In both types of therapy, scientists need something to transport either the entire gene or a recombinant DNA to the cell's nucleus, where the chromosomes and DNA reside. In essence, vectors are molecular delivery trucks. One of the first and most popular vectors developed were viruses because they invade cells as part of the natural infection process. Viruses have the potential to be excellent vectors because they have a specific relationship with the host in that they colonize certain cell types and tissues in specific organs. As a result, vectors are chosen according to their attraction to certain cells and areas of the body.

One of the first vectors used was the retrovirus. Because these viruses are easily cloned (artificially reproduced) in the laboratory, scientists have studied them extensively and learned a great deal about their biological action. They have also learned how to remove the genetic information which governs viral replication, thus reducing the chances of infection.

Retroviruses work best in actively dividing cells, but cells in the body are relatively stable and do not divide often. As a result, these cells are used primarily for *ex vivo* (outside the body) manipulation. First, the cells are removed from the patient's body, and the virus, or vector, carrying the gene is inserted into them. Next, the cells are placed into a nutrient culture where they grow and replicate. Once enough cells are gathered, they are returned to the body, usually by injection into the bloodstream. Theoretically, as long as these cells survive, they will provide the desired therapy.

Another class of viruses, called the adenoviruses, may also prove to be good gene vectors. These viruses can effectively infect nondividing cells in the body, where the desired gene product is then expressed naturally. In addition to being a more efficient approach to gene transportation, these viruses, which cause respiratory infections, are more easily purified and made stable than retroviruses, resulting in less chance of an unwanted viral infection. However, these viruses live for several days in the body, and some concern

surrounds the possibility of infecting others with the viruses through sneezing or coughing. Other viral vectors include **influenza** viruses, Sindbis virus, and a herpes virus that infects nerve cells.

Scientists have also delved into nonviral vectors. These vectors rely on the natural biological process in which cells uptake (or gather) macromolecules. One approach is to use liposomes, globules of fat produced by the body and taken up by cells. Scientists are also investigating the introduction of raw recombinant DNA by injecting it into the bloodstream or placing it on microscopic beads of gold shot into the skin with a "gene-gun." Another possible vector under development is based on dendrimer molecules. A class of polymers (naturally occurring or artificial substances that have a high molecular weight and formed by smaller molecules of the same or similar substances), is "constructed" in the laboratory by combining these smaller molecules. They have been used in manufacturing Styrofoam, polyethylene cartons, and Plexiglass. In the laboratory, dendrimers have shown the ability to transport genetic material into human cells. They can also be designed to form an affinity for particular cell membranes by attaching to certain sugars and protein groups.

History of gene therapy

In the early 1970s, scientists proposed "gene surgery" for treating inherited diseases caused by faulty genes. The idea was to take out the disease-causing gene and surgically implant a gene that functioned properly. Although sound in theory, scientists, then and now, lack the biological knowledge or technical expertise needed to perform such a precise surgery in the human body.

However, in 1983, a group of scientists from Baylor College of Medicine in Houston, Texas, proposed that gene therapy could one day be a viable approach for treating Lesch-Nyhan disease, a rare neurological disorder. The scientists conducted experiments in which an enzyme-producing gene (a specific type of protein) for correcting the disease was injected into a group of cells for replication. The scientists theorized the cells could then be injected into people with Lesch-Nyhan disease, thus correcting the genetic defect that caused the disease.

As the science of genetics advanced throughout the 1980s, gene therapy gained an established foothold in the minds of medical scientists as a promising approach to treatments for specific diseases. One of the major reasons for the growth of gene therapy was scientists' increasing ability to identify the specific genetic malfunctions that caused inherited diseases. Interest grew as further studies of DNA and chromosomes (where genes reside) showed that specific genetic abnormalities in one or more genes occurred in successive generations of certain family members who suffered from diseases like intestinal cancer, manic-depression, Alzheimer's disease, **heart disease**, diabetes, and many more. Although the genes may not be the only cause of the disease in all cases, they may make certain individuals more susceptible to developing the disease because of environmental influences, like **smoking**, pollution, and **stress**. In fact, some scientists theorize that all diseases may have a genetic component.

On September 14, 1990, a four-year-old girl with a genetic disorder that prevented her body from producing a crucial enzyme became the first person to undergo gene therapy in the United States. Because her body could not produce adenosine deaminase (ADA), she had a weakened immune system, making her extremely susceptible to severe, life-threatening infections. W. French Anderson and colleagues at the National Institutes of Health's Clinical Center in Bethesda, Maryland, took white blood cells (which are crucial to proper immune system functioning) from the girl, inserted ADA producing genes into them, and then transfused the cells back into the patient. Although the young girl continued to show an increased ability to produce ADA, debate arose as to whether the improvement resulted from the gene therapy or from an additional drug treatment she received.

Nevertheless, a new era of gene therapy began as more and more scientists sought to conduct clinical trial (testing in humans) research in this area. In that same year, gene therapy was tested on patients with **melanoma** (**skin cancer**). The goal was to help them produce antibodies (disease fighting substances in the immune system) to battle the cancer.

These experiments have spawned an ever-growing number of attempts at gene therapies designed to perform a variety of functions in the body. For example, a gene therapy for cystic fibrosis aims to supply a gene that alters cells, enabling them to produce a specific protein to battle the disease. Another approach was used for brain cancer patients, in which the inserted gene was designed to make the cancer cells more likely to respond to drug treatment. Gene therapy for patients who have artery blockage, which can lead to strokes, induces the growth of new blood vessels near clogged arteries, thus ensuring normal blood circulation.

Currently, there are a host of new gene therapy agents in clinical trials. In the United States, both

WWW.BOOKBAZ.IR

nucleic acid-based (*in vivo*) treatments and cell-based (*ex vivo*) treatments are being investigated. Nucleic acid-based gene therapy uses vectors (like viruses) to deliver modified genes to target cells. Cell-based gene therapy techniques remove cells from the patient in order to genetically alter them then reintroduce them to the patient's body. Presently, gene therapies for the following diseases are being developed: cystic fibrosis (using adenoviral vector), HIV infection (cell-based), malignant melanoma (cell-based), Duchenne **muscular dystrophy** (cell-based), hemophilia B (cell-based), **kidney cancer** (cell-based), **Gaucher disease** (retroviral vector), **breast cancer** (retroviral vector), and lung cancer (retroviral vector). When a cell or individual is treated using gene therapy and successful incorporation of engineered genes has occurred, the cell or individual is said to be *transgenic*.

The medical establishment's contribution to transgenic research has been supported by increased government funding. In 1991, the U.S. government provided $58 million for gene therapy research, with increases in funding of $15–40 million dollars a year over the following four years. With fierce competition over the promise of societal benefit in addition to huge profits, large pharmaceutical corporations have moved to the forefront of transgenic research. In an effort to be first in developing new therapies, and armed with billions of dollars of research funds, such corporations are making impressive strides toward making gene therapy a viable reality in the treatment of once elusive diseases.

Diseases targeted for treatment by gene therapy

The potential scope of gene therapy is enormous. More than 5,000 diseases have been identified as resulting directly from abnormal genes, and countless others that may be partially influenced by a person's genetic makeup. Initial research has concentrated on developing gene therapies for diseases whose genetic origins have been established and for other diseases that can be cured or ameliorated by substances genes produce.

The following are examples of potential gene therapies. People suffering from cystic fibrosis lack a gene needed to produce a salt-regulating protein. This protein regulates the flow of chloride into epithelial cells, (the cells that line the inner and outer skin layers) which cover the air passages of the nose and lungs. Without this regulation, patients with cystic fibrosis build up a thick mucus that makes them prone to lung infections. A gene therapy technique to correct this abnormality might employ an adenovirus to transfer a normal copy of what scientists call the cystic fibrosis transmembrane conductance regulator, or CTRF, gene. The gene is introduced into the patient by spraying it into the nose or lungs.

Familial **hypercholesterolemia** (FH) is also an inherited disease, resulting in the inability to process **cholesterol** properly, which leads to high levels of artery-clogging fat in the bloodstream. Patients with FH often suffer heart attacks and strokes because of blocked arteries. A gene therapy approach used to battle FH is much more intricate than most gene therapies because it involves partial surgical removal of patients' livers (*ex vivo* transgene therapy). Corrected copies of a gene that serve to reduce cholesterol build-up are inserted into the liver sections, which are then transplanted back into the patients.

Gene therapy has also been tested on patients with **AIDS**. AIDS is caused by the human **immunodeficiency** virus (HIV), which weakens the body's immune system to the point that sufferers are unable to fight off diseases like pneumonias and cancer. In one approach, genes that produce specific HIV proteins have been altered to stimulate immune system functioning without causing the negative effects that a complete HIV molecule has on the immune system. These genes are then injected in the patient's bloodstream. Another approach to treating AIDS is to insert, via white blood cells, genes that have been genetically engineered to produce a receptor that would attract HIV and reduce its chances of replicating.

Several cancers also have the potential to be treated with gene therapy. A therapy tested for melanoma, or skin cancer, involves introducing a gene with an anticancer protein called **tumor necrosis factor** (TNF) into test tube samples of the patient's own cancer cells, which are then reintroduced into the patient. In brain cancer, the approach is to insert a specific gene that increases the cancer cells' susceptibility to a common drug used in fighting the disease.

Gaucher disease is an inherited disease caused by a mutant gene that inhibits the production of an enzyme called glucocerebrosidase. Patients with Gaucher disease have enlarged livers and spleens and eventually their bones deteriorate. Clinical gene therapy trials focus on inserting the gene for producing this enzyme.

Gene therapy is also being considered as an approach to solving a problem associated with a surgical procedure known as balloon **angioplasty**. In this procedure, a stent (in this case, a type of tubular scaffolding) is used to open the clogged artery. However, in response to the **trauma** of the stent insertion, the body

initiates a natural healing process that produces too many cells in the artery and results in restenosis, or reclosing of the artery. The gene therapy approach to preventing this unwanted side effect is to cover the outside of the stents with a soluble gel. This gel contains vectors for genes that reduce this overactive healing response.

The Human Genome Project

Although great strides have been made in gene therapy in a relatively short time, its potential usefulness has been limited by lack of scientific data concerning the multitude of functions that genes control in the human body. For instance, it is now known that the vast majority of genetic material does not store information for the creation of proteins, rather, it is involved in the control and regulation of gene expression, and is therefore much more difficult to interpret. Even so, each individual cell in the body carries thousands of genes coding for proteins, with some estimates as high as 150,000 genes. For gene therapy to advance to its full potential, scientists must discover the biological role of each of these individual genes and where the base pairs that make them up are located on DNA.

To address this issue, the National Institutes of Health initiated the Human Genome Project in 1990. Led initially by James D. Watson, one of the co-discoverers of the chemical makeup of DNA, the project's 15-year goal was to map the entire human genome (a combination of the words gene and chromosomes). Watson was replaced in 1993 by Dr. Francis Collins, and the name of the project's center was officially changed to the National Human Genome Research Institute (NHGRI) in 1997. A genome map would clearly identify the location of all genes as well as the more than three billion base pairs that make them up. With a precise knowledge of gene locations and functions, scientists may one day be able to conquer or control diseases that have plagued humanity for centuries.

Scientists working at NHGRI have identified an average of one new gene a day, but many expect this rate of discovery to increase. Their goal was to determine the exact location of all the genes on human DNA and the exact sequence of the base pairs that make them up by 2005. A "rough draft" of the genome was finished in 2000, with the complete genome essentially sequenced by April 2003, two years earlier than planned. A number of regions of the genome, however, remain incompletely sequenced as of 2014. These include the central regions of the chromosomes, known as centromeres, and the end regions of the chromosomes, the telomeres. Both these regions are highly repetitive DNA sequences millions of base pairs in length that are difficult to sequence given the limits of current technology.

Some of the genes already identified through the Human Genome Project include a gene that predisposes people to **obesity**, one associated with programmed cell death (apoptosis), a gene that guides HIV viral reproduction, and the genes of inherited disorders like Huntington disease, Lou Gehrig's disease, and some colon and breast cancers. As the human genome is completed, there will be more information available for gene therapy research and implementation.

Future of gene therapy

Gene therapy seems elegantly simple in its concept: supply the human body with a gene that can correct a biological malfunction that causes a disease. However, there are many obstacles and some distinct questions concerning the viability of gene therapy. For example, viral vectors must be carefully controlled lest they infect the patient with a viral disease. Some vectors, like retroviruses, can also enter cells functioning properly and interfere with the natural biological processes, possibly leading to other diseases. Other viral vectors, like the adenoviruses, are often recognized and destroyed by the immune system so their therapeutic effects are short-lived. Maintaining gene expression so that the gene will perform its role properly after vector delivery is difficult. As a result, some therapies need to be repeated often to provide long-lasting benefits.

One of the most pressing issues, however, is gene regulation. Genes work in concert to regulate their functioning. In other words, several genes may play a part in turning other genes on and off. For example, certain genes work together to stimulate cell division and growth, but if these are not regulated, the inserted genes could cause tumor formation and cancer. Another difficulty is learning how to make the gene go into action only when needed. For the best and safest therapeutic effort, a specific gene should turn on, for example, when certain levels of a protein or enzyme are low and must be replaced. But the gene should also remain dormant when not needed to ensure it does not oversupply a substance and disturb the body's delicate chemical makeup.

One approach to gene regulation is to attach other genes that detect certain biological activities and then react as a type of automatic off-and-on switch that

WWW.BOOKBAZ.IR

regulates the activity of the other genes according to biological cues. Although still in the rudimentary stages, researchers are making headway in inhibiting some gene functioning by using a synthetic DNA to block gene transcriptions (the copying of genetic information). This approach may have implications for gene therapy.

Ethics of gene therapy

While gene therapy holds promise as a revolutionary approach to treating disease, ethical concerns over its use and ramifications have been expressed by scientists and lay people alike. For example, since much needs to be learned about how these genes actually work and their long-term effect, is it ethical to test these therapies on humans, where they could have a disastrous result? As with most clinical trials concerning new therapies, including many drugs, the patients participating in these studies have usually not responded to more established therapies and are often so ill the novel therapy is their only hope for long-term survival.

Another questionable outgrowth of gene therapy is that scientists could possibly manipulate genes to genetically control traits in human offspring that are not health-related. For example, perhaps a gene could be inserted to ensure that a child would not be bald, a seemingly harmless goal. However, what if genetic manipulation was used to alter skin color, prevent homosexuality, or ensure good looks? If a gene is found that can enhance intelligence of children who are not yet born, will everyone in society, the rich and the poor, have access to the technology or will it be so expensive only the elite can afford it?

The Human Genome Project, which plays such an integral role for the future of gene therapy, also has social repercussions. If individual genetic codes can be determined, will such information be used against people? For example, will someone more susceptible to a disease have to pay higher insurance premiums or be denied health insurance altogether? Will employers discriminate between two potential employees, one with a "healthy" genome and the other with genetic abnormalities?

Some of these concerns can be traced back to the eugenics movement popular in the first half of the twentieth century. This genetic "philosophy" was a societal movement that encouraged people with "positive" traits to reproduce while those with less desirable traits were sanctioned from having children. Eugenics was used to pass strict immigration laws in the United States, barring less suitable people from entering the country lest they reduce the quality of the country's collective gene pool. Probably the most notorious example of eugenics in action was the rise of Nazism in Germany, which resulted in the Eugenic Sterilization Law of 1933. The law required sterilization for those suffering from certain disabilities and even for some who were simply deemed "ugly." To ensure that this novel science is not abused, many governments have established organizations specifically for overseeing the development of gene therapy. In the United States, the Food and Drug Administration (FDA) and the National Institutes of Health (NIH) require scientists to take a precise series of steps and meet stringent requirements before approving clinical trials.

In fact, gene therapy has been immersed in more controversy and surrounded by more scrutiny in both the health and ethical arena than most other technologies (except, perhaps, for cloning) that promise to substantially change society. Despite the health and ethical questions surrounding gene therapy, the field will continue to grow and is likely to change medicine faster than any previous medical advancement.

Katherine Hunt, MS
REVISED BY REBECCA J. FREY, PhD

General adaptation syndrome

Definition

General adaptation syndrome, or GAS, is a term used to describe the body's short-term and long-term reactions to **stress**.

Stressors in humans include such physical stressors as **starvation**, being hit by a car, or suffering through severe weather. Additionally, humans can suffer such emotional or mental stressors as the loss of a loved one, the inability to solve a problem, or even having a difficult day at work.

Description

Originally described by Hans Selye (1907–1982), an Austrian-born physician who emigrated to Canada in 1939, the general adaptation syndrome represents a three-stage reaction to stress. Selye explained his choice of terminology as follows: "I call this syndrome *general* because it is produced only by agents which have a general effect upon large portions of the body. I call it *adaptive* because it stimulates defense. . .I call it a *syndrome* because its individual manifestations are coordinated and even partly dependent upon each other."

Selye thought that the general adaptation syndrome involved two major systems of the body, the nervous system and the endocrine (or hormonal) system. He then went on to outline what he considered as three distinctive stages in the syndrome's evolution. He called these stages the alarm reaction (AR), the stage of resistance (SR), and the stage of exhaustion (SE).

Stage 1: Alarm reaction (AR)

The first stage of the general adaptation stage, the alarm reaction, is the immediate reaction to a stressor. In the initial phase of stress, humans exhibit a "fight or flight" response, which prepares the body for physical activity. However, this initial response can also decrease the effectiveness of the immune system, making persons more susceptible to illness during this phase.

Stage 2: Stage of resistance (SR)

Stage 2 might also be named the stage of adaptation, instead of the stage of resistance. During this phase, if the stress continues, the body adapts to the stressors it is exposed to. Changes at many levels take place in order to reduce the effect of the stressor. For example, if the stressor is starvation (possibly due to anorexia), the person might experienced a reduced desire for physical activity to conserve energy, and the absorption of nutrients from food might be maximized.

Stage 3: Stage of exhaustion (SE)

At this stage, the stress has continued for some time. The body's resistance to the stress may gradually be reduced, or may collapse quickly. Generally, this means the immune system, and the body's ability to resist disease, may be almost totally eliminated. Patients who experience long-term stress may succumb to heart attacks or severe infection due to their reduced immunity. For example, a person with a stressful job may experience long-term stress that might lead to high blood pressure and an eventual **heart attack**.

Stress, a useful reaction?

The reader should note that Dr. Selye did not regard stress as a purely negative phenomenon; in fact, he frequently pointed out that stress is not only an inevitable part of life but results from intense joy or pleasure as well as fear or **anxiety**. "Stress is not even necessarily bad for you; it is also the spice of life, for any emotion, any activity, causes stress." Some later researchers have coined the term "eustress" or pleasant stress, to reflect the fact that such positive experiences as a job promotion, completing a degree or training program, marriage, travel, and many others are also stressful.

Selye also pointed out that human perception of and response to stress is highly individualized; a job or sport that one person finds anxiety-provoking or exhausting might be quite appealing and enjoyable to someone else. Looking at one's responses to specific stressors can contribute to better understanding of one's particular physical, emotional, and mental resources and limits.

Causes and symptoms

Stress is one cause of general adaptation syndrome. The results of unrelieved stress can manifest

WWW.BOOKBAZ.IR

KEY TERMS

Adjustment disorder—A disorder defined by the development of significant emotional or behavioral symptoms in response to a stressful event or series of events within the normal range of human experience.

Cortisol—A steroid hormone released by the cortex (outer portion) of the adrenal gland when a person is under stress.

Eustress—A term that is sometimes used to refer to positive stress.

Stress management—A set of techniques and programs intended to help people deal more effectively with stress in their lives by analyzing the specific stressors and taking positive actions to minimize their effects. Most stress management programs deal with job stress and workplace issues.

Stressor—A stimulus or event that provokes a stress response in an organism. Stressors can be categorized as acute or chronic, and as external or internal to the organism.

as **fatigue**, irritability, difficulty concentrating, and difficulty sleeping. Persons may also experience other symptoms that are signs of stress. Persons experiencing unusual symptoms, such as hair loss, without another medical explanation might consider stress as the cause.

The general adaptation syndrome is also influenced by such universal human variables as overall health and nutritional status, sex, age, ethnic or racial background, level of education, socioeconomic status (SES), genetic makeup, etc. Some of these variables are biologically based and difficult or impossible to change. For example, recent research indicates that men and women respond somewhat differently to stress, with women being more likely to use what is called the "tend and befriend" response rather than the classical "fight or flight" pattern. These researchers note that most of the early studies of the effects of stress on the body were conducted with only male subjects.

Selye's observation that people vary in their perceptions of stressors was reflected in his belief that the stressors themselves are less dangerous to health than people's maladaptive responses to them. He categorized certain diseases, ranging from cardiovascular disorders to inflammatory diseases and mental disorders as "diseases of adaptation," regarding them as "largely due to errors in our adaptaive response to stress" rather than the direct result of such outside factors as germs, toxic substances, etc.

Diagnosis

GAS by itself is not an official diagnostic category but rather a descriptive term. A person who consults a doctor for a stress-related physical illness may be scheduled for blood or urine tests to measure the level of cortisol or other stress-related hormones in their body, or imaging studies to evaluate possible abnormalities in their endocrine glands if the doctor thinks that these tests may help to establish or confirm a diagnosis.

The American Psychiatric Association (APA) recognizes stress as a factor in **anxiety disorders**, particularly **post-traumatic stress disorder** (PTSD) and **acute stress disorder** (ASD). These two disorders are defined as symptomatic reactions to extreme traumatic stressors (war, natural or transportation disasters, criminal assault, **abuse**, hostage situations, etc.) and differ chiefly in the time frame in which the symptoms develop. The APA also has a diagnostic category of **adjustment disorders**, which are characterized either by excessive reactions to stressors within the normal range of experience (e.g., academic examinations, relationship breakups, being fired from a job) or by significant impairment in the person's occupational or social functioning.

Treatment

Treatment of stress-related illnesses typically involves one or more **stress reduction** strategies. Stress reduction strategies generally fall into one of three categories: avoiding stressors; changing one's reaction to the stressor(s); or relieving stress after the reaction to the stressor(s). Many mainstream as well as complementary or alternative (CAM) strategies for stress reduction, such as exercising, listening to music, **aromatherapy**, and massage relieve stress after it occurs.

Many psychotherapeutic approaches attempt to modify the patient's reactions to stressors. These approaches often include an analysis of the patient's individual patterns of response to stress; for example, one commonly used set of categories describes people as "speed freaks," "worry warts," "cliff walkers," "loners," "basket cases," and "drifters." Each pattern

has a recommended set of skills that the patient is encouraged to work on; for example, worry warts are advised to reframe their anxieties and then identify their core values and goals in order to take concrete action about their worries. In general, persons wishing to improve their management of stress should begin by consulting a medical professional with whom they feel comfortable to discuss which option, or combination of options, they can use.

Selye himself recommended an approach to stress that he described as "living wisely in accordance with natural laws." In his now-classic book *The Stress of Life* (1956), he discussed the following as important dimensions of living wisely:

- Adopting an attitude of gratitude toward life rather than seeking revenge for injuries or slights.
- Acting toward others from altruistic rather than self-centered motives.
- Retaining a capacity for wonder and delight in the genuinely good and beautiful things in life.
- Finding a purpose for one's life and expressing one's individuality in fulfilling that purpose.
- Keeping a healthy sense of modesty about one's goals or achievements.

General anesthetic *see* **Anesthesia, general**

General surgery

Definition

General surgery is the treatment of injury, deformity, or disease using operative procedures. It also includes procedures for diagnostic purposes.

Purpose

General surgery procedures are frequently performed to alleviate suffering when a cure is unlikely through medication alone. It includes routine procedures performed in a physician's office, such as excision of lesions, as well as more complicated operations requiring a medical team in a hospital setting, such as laparoscopic **cholecystectomy** (removal of the gallbladder). Areas of the body treated by general surgery include the abdominal organs, such as the stomach, liver, intestines, and appendix; breasts; thyroid gland; salivary glands; some arteries and veins; the inguinal region; and the skin. It also includes procedures performed on the alimentary tract, otherwise known as the digestive tract. The brain, heart, lungs, eyes, feet, kidneys, bladder, and reproductive organs—to name only a few—are areas that require more specialized surgical repair.

New methods and techniques are less invasive than older practices, permitting procedures that were considered impossible in the past. For example, **microsurgery** has been used to reattach severed body parts by successfully reconnecting small blood vessels and nerves. Laparoscopic techniques are more efficient, promote more rapid healing, leave smaller **scars**, and have lower postoperative infection rates than traditional invasive techniques.

Description

General surgery is performed by a physician with specialized training in surgery. It is most commonly performed in an outpatient facility adjacent to a

WWW.BOOKBAZ.IR

hospital or in an operating room of a hospital. Very minor procedures, such as **abscess incision and drainage** or the removal of a small or superficial foreign body, may be performed in a professional office.

In earlier times, surgery was a dangerous and dirty practice. Through the middle of the nineteenth century, the number of people who died from surgery approximately equaled the number of those who were cured. With the discovery and development of general **anesthesia** in the mid-nineteenth century, surgery became more humane. As knowledge about infections grew and sterile practices were introduced into the operating room, surgery became more successful. The last 50 years have brought continued advancements.

General surgery experienced major advances with the introduction of the endoscope. This is an instrument for visualizing the interior of a body canal or a hollow organ. Endoscopic surgery relies on this pencil-thin instrument, equipped with its own lighting system and small video camera. The endoscope is inserted through tiny incisions called portals. While viewing the procedure on a video screen, the surgeon then operates with various other small, precise instruments inserted through one or more of the portals. The specific area of the body to be treated determines the type of endoscopic surgery performed. For example, **colonoscopy** uses an endoscope (which can also be equipped with a device for obtaining tissue samples) for visual examination of the colon. Gastroscopy uses an endoscope inserted through the mouth to examine the interior of the stomach. **Arthroscopy** refers to joint surgery. Abdominal procedures are called laparoscopies.

Endoscopy is frequently used in both treatment and diagnosis involving the digestive and female reproductive systems. Endoscopy has advantages over many other surgical procedures, resulting in a quicker recovery and shorter hospital stays. This noninvasive technique is used for appendectomies, gallbladder surgery, hysterectomies, and the repair of shoulder and knee ligaments; however, endoscopy has limitations such as complications and operating expense. Endoscopy does not offer advantages over conventional surgery in all procedures; however, with continued technical advances and increasingly experienced general surgeons, additional noninvasive surgical procedures will become more common and include more procedures.

Ambulatory surgery is also known as same-day or outpatient surgery. Surgical procedures in this category usually require two hours or less and involve minimal blood loss and a short recovery time. In the majority of surgical cases, oral medications control postoperative **pain**. Cataract removal, **laparoscopy**, **tonsillectomy**, repair of broken bones, **hernia repair**, and a wide range of cosmetic procedures are common same-day surgical procedures. Many individuals prefer the convenience and atmosphere of ambulatory surgery centers, as there is less competition for attention with more serious surgical cases. These centers are accredited by the Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations) or the Accreditation Association for Ambulatory Health Care.

Surgical training

All surgeons receive similar training in the first two years of their residency (post-medical school) training. General surgery is considered a surgical specialty and involves procedures that may involve multiple body systems and regions. General surgeons typically differ from other surgical specialties in the operations that they perform. This difference is most easily understood by exclusion. For example, procedures involving nerves or the brain are usually performed by neurosurgeons. Surgeons having specialized training during the final three years of their residency period similarly focus on other regions of the body. General surgeons may perform such procedures in the absence of other surgeons with specialized training; however, these situations are the exception rather than the rule. Some surgical procedures require a general surgeon and a surgeon from another specialty, such as urology or gynecology. **Trauma** patients may require several surgeons from different specialties to perform procedures.

Shortage of surgeons

The United States is experiencing a shortage of general surgeons in the twenty-first century. There were approximately 795,000 practicing physicians in 2010, but only 24,000 restricted their practices to general surgery. According to the American College of Surgeons, around 1,000 residents complete general surgery training each year, but that number has remained stagnant since 1980, despite a growing population. A lack of surgeons means longer patient wait times, which affects overall care.

Precautions

Before undergoing general surgery, people who are obese, smoke, have bleeding tendencies, or are over 60 must follow special precautions, as do persons who have recently experienced illnesses, including **pneumonia** or a

heart attack. People taking medications such as heart and blood pressure medicine, blood thinners, **muscle relaxants**, tranquilizers, anticonvulsants, insulin, or sedatives may require special laboratory tests prior to surgery and special monitoring during surgery. Extra precautions may be necessary for individuals using mind-altering drugs such as **narcotics**, psychedelics, hallucinogens, **marijuana**, sedatives, or cocaine since these drugs may interact with the anesthetic agents used during surgery.

Preparation

The preparation of patients for surgery has advanced significantly with improved diagnostic techniques and procedures. Before surgery, a candidate may be asked to undergo a series of tests, including blood and urine studies, x rays, and specific heart studies if the person's past medical history or **physical examination** warrants this testing. Before any surgical procedure, the physician will explain the nature of the surgery needed, the reason for the procedure, and the anticipated outcome. The risks involved will be discussed, along with the types of anesthesia to be utilized. The expected length of recovery and limitations imposed during the recovery period are also explained in detail before any surgical procedure.

Surgical procedures most often require some type of anesthetic. Some procedures require only local anesthesia, produced by injecting the anesthetic agent into the skin near the site of the operation. The person remains awake with this form of medication. Injecting anesthetic agents near a primary nerve located adjacent to the surgical site produces block anesthesia (also known as regional anesthesia), which is a more extensive local anesthesia. The person remains conscious, but is usually sedated. General anesthesia involves injecting anesthetic agents into the bloodstream or inhaling medicines through a mask placed over the patient's face. During general anesthesia, an individual is asleep and an airway tube is usually placed into the windpipe (trachea) to help keep the airway open. This is known as intubation.

As part of the preoperative preparation, surgical patients will receive printed educational material and may be asked to review additional audio or video information. They will be instructed to shower or bathe the evening before or morning of surgery and may be asked to scrub the operative site with a special antibacterial soap. Instructions will also be given to remain NPO (nothing by mouth), which means the patient should not eat or drink anything, including water, for a determined period of time prior to the surgical procedure.

KEY TERMS

Appendectomy—Removal of the appendix.

Endoscope—Instrument for visual examination of the inside of a body canal or a hollow organ such as the stomach, colon, or bladder.

Hysterectomy—Surgical removal of part or all of the uterus.

Laparoscopic cholecystectomy—Removal of the gallbladder using a laparoscope, a fiber-optic instrument inserted through the abdomen.

Microsurgery—Surgery on small body structures or cells performed with the aid of a microscope and other specialized instruments.

Portal—An entrance or a means of entrance.

Results

Advances in diagnostic and surgical techniques have greatly increased the success rate of general surgery. Contemporary procedures are less invasive than those practiced a decade or more ago. The results include reduced length of hospital stays, shortened recovery times, decreased postoperative pain, and decreases in the size and extent of surgical incisions. The length of time required for a full recovery varies with the procedure.

Risks

A risk associated with general surgery is the potential for postoperative complications. These complications include, but are not limited to, pneumonia, internal bleeding, and wound infection, as well as adverse reactions to anesthesia.

Morbidity and mortality rates

Mortality from general surgical procedures is uncommon. The most common causes of mortality are adverse reactions to anesthetic agents or drugs used to control pain, postsurgical clot formation in the veins, and postsurgical heart attacks or strokes.

Abnormal results from general surgery include persistent pain, swelling, redness, drainage, or bleeding in the surgical area and surgical wound infection, resulting in slow healing.

WWW.BOOKBAZ.IR

Alternatives

For the removal of diseased or nonvital tissue, there is no alternative to surgery. Alternatives to general surgery depend on the condition being treated. Medications, **acupuncture**, or hypnosis can be used to relieve pain. Radiation is an occasional alternative for shrinking growths. **Chemotherapy** may be used to treat cancer. Additionally, some foreign bodies may remain in the body without harm.

REVISED BY TAMMY ALLHOFF, CST/CSFA, AAS

Generalized anxiety disorder

Definition

Generalized **anxiety** disorder is a condition characterized by "free floating" anxiety or apprehension not linked to a specific cause or situation.

Description

Some degree of fear and anxiety is perfectly normal. In the face of real danger, fear makes people more alert and prepares the body to fight or flee (the "fight or flight" response). When people are afraid, their hearts beat faster and they breathe faster in anticipation of the physical activity that will be required of them. Sometimes people can become anxious even when there is no identifiable cause, and this anxiety can become overwhelming and very unpleasant, interfering with their daily lives. People with debilitating anxiety are said to be suffering from **anxiety disorders**, such as **phobias**, panic disorders, and generalized anxiety disorder. The person with generalized anxiety disorder generally has chronic (officially, having more days with anxiety than not for at least six months), recurrent episodes of anxiety that can last days, weeks, or even months.

Causes and symptoms

Generalized anxiety disorder afflicts between 2% and 3% of the general population, and is slightly more common in women than in men. It accounts for almost one-third of cases referred to psychiatrists by general practitioners.

Generalized anxiety disorder may result from a combination of causes. Some people are genetically predisposed to developing it. Psychological traumas that occur during childhood, such as prolonged separation from parents, may make people more vulnerable as well. Stressful life events, such as a move, a major job change, the loss of a loved one, or a divorce, can trigger or contribute to the anxiety.

Psychologically, the person with generalized anxiety disorder may develop a sense of dread for no apparent reason—the irrational feeling that some nameless catastrophe is about to happen. Physical symptoms similar to those found with **panic disorder** may be present, although not as severe. They may include trembling, sweating, heart **palpitations** (the feeling of the heart pounding in the chest), nausea, and "butterflies in the stomach."

According to the *Diagnostic and Statistical Manual of Mental Disorders,* a person must have at least three of the following symptoms, with some being present more days than not for at least six months, in order to be diagnosed with generalized anxiety disorder:

- restlessness or feeling on edge
- easily fatigued
- difficulty concentrating
- irritability
- muscle tension
- sleep disturbance

While generalized anxiety disorder is not completely debilitating, it can compromise a person's effectiveness and quality of life.

Diagnosis

Anyone with chronic anxiety for no apparent reason should see a physician. The physician may diagnose the condition based on the patient's description of the physical and emotional symptoms. The doctor will also try to rule out other medical conditions that may be causing the symptoms, such as excessive **caffeine** use, thyroid disease, **hypoglycemia**, cardiac problems, or drug or alcohol withdrawal. Psychological conditions, such as depressive disorder with anxiety, will also need to be ruled out.

In June 2004, the Anxiety Disorders Association of America released follow-up guidelines to help primary care physicians better diagnose and manage patients with generalized anxiety disorder. They include considering the disorder when medical causes for general, vague physical complaints cannot be ruled out. Since generalized anxiety disorder often co-occurs with **mood disorders** and substance abuse, the clinician may have to treat these conditions as well, and, therefore, must consider them in making the diagnosis.

Treatment

Drugs

Over the short term, a group of tranquilizers called **benzodiazepines**, such as clonazepam (Klonipin), may help ease the symptoms of generalized anxiety disorder. Sometimes **antidepressant drugs**, such as amitryptiline (Elavil), or **selective serotonin reuptake inhibitors** (SSRIs), such as paroxetine (Paxil), escitalopram (Lexapro), and venlafaxine (Effexor), which also has norepinephrine, may be preferred. Other SSRIs are fluoxetine (Prozac) and sertraline (Zoloft).

WWW.BOOKBAZ.IR

KEY TERMS

Cognitive behavioral therapy—A psychotherapeutic approach that aims at altering cognitions—including thoughts, beliefs, and images—as a way of altering behavior.

Panic attack—A time-limited period of intense fear accompanied by physical and cognitive symptoms. Panic attacks may be unexpected or triggered by specific internal or external cues.

Alternatives

Psychotherapy can be effective in treating generalized anxiety disorder. The therapy may take many forms. In some cases, psychodynamically-oriented psychotherapy can help patients work through this anxiety and solve problems in their lives. Cognitive behavioral therapy aims to reshape the way people perceive and react to potential stressors in their lives. Relaxation techniques have also been used in treatment, as well as in prevention efforts.

Prognosis

When properly treated, most patients with generalized anxiety disorder experience improvement in their symptoms.

Prevention

While preventive measures have not been established, a number of techniques may help manage anxiety, such as relaxation techniques, breathing exercises, and distraction—putting the anxiety out of one's mind by focusing thoughts on something else.

Genetic counseling

Definition

Genetic counseling is a communication process by which personal genetic risk information is translated into practical information for families. Genetic counselors are commonly healthcare professionals with specialized training and experience in the areas of medical genetics and counseling. They work as members of a healthcare team, providing individuals and families with information on the nature, inheritance, and implications of genetic disorders to help them make informed medical and personal decisions.

Purpose

Specifically, the process of genetic counseling assists families by:

- Helping families understand information about birth defects or genetic disorders. This includes explaining patterns of inheritance, recurrence risks, natural history of diseases, and genetic testing options.
- Providing nondirective supportive counseling regarding emotional issues related to a diagnosis or testing options.

- Helping individuals or families make decisions that they are comfortable with based on their personal ethical and religious standards.
- Connecting families with appropriate resources, such as support groups or specific types of medical clinics, locally and nationally.

As of 2014, 34 universities were offering genetic counseling study programs in the United States and Canada meeting the rigorous accreditation criteria established by the American Board of Genetic Counseling (ABGC). Most genetic counseling programs are two-year programs that include course work, clinical rotations and an independent research project. Most applicants enter the field from variety of disciplines, including biology, genetics, psychology, and nursing.

Description

Genetic counselors work with people concerned about the risk of an inherited disease. These patients represent several different patient populations. Prenatal genetic counseling is provided to couples that have an increased risk for **birth defects** or inherited conditions and are expecting a child or planning a **pregnancy**. Pediatric genetic counseling is provided to families with children suspected of having a genetic disorder or with children previously diagnosed with a genetic disorder. Adult genetic counseling is provided to adults with clinical features of an inherited disease or a family history of an inherited disease. Cancer genetic counseling is provided to those with a strong family history of certain types of cancer.

Prenatal genetic counseling

There are several different reasons a person or couple may seek prenatal genetic counseling. If a woman is age 35 or older and pregnant, there is an increased chance that the fetus may have a change in the number of chromosomes present. Changes in chromosome number may lead to intellectual disabilities (ID) and birth defects. **Down syndrome** is the most common change in chromosome number that occurs more often in the fetuses of older women. Couples may seek prenatal genetic counseling because of abnormal results of screening tests performed during pregnancy. A blood test called the alpha fetal protein (AFP) test is offered to all pregnant women. This blood test screens for Down syndrome, open spine defects (**spina bifida**) and another type of ID caused by a change in chromosome number called Trisomy 18. When this test is abnormal, further tests are offered to get more information about the chance of these conditions in the fetus. Another reason that people seek prenatal genetic counseling is a family history of birth defects or inherited diseases. In some cases, blood tests on the parents may be available to indicate if their children would be at risk of being affected. Genetic counselors assess risk in each case, help patients understand their risks and explore how patients feel about or cope with these risks.

Prenatal tests that are offered during genetic counseling include level II ultrasounds, maternal serum AFP screening, **chorionic villus sampling** (CVS), and **amniocentesis**. Level II **ultrasound** is a detailed ultrasound surveying fetal anatomy for birth defects. Ultrasound is limited to detection of structural changes in anatomy and cannot detect changes in chromosome number. The maternal serum AFP screening is used to indicate if a pregnant woman has a higher or lower chance of certain birth defects. This test can only change the chances for a birth defect. The screening cannot diagnose a birth defect. CVS is a way of learning how many chromosomes is present in a fetus. A small piece of placental tissue is obtained for these studies during the tenth to twelfth weeks of pregnancy. Amniocentesis is also a way of learning how many chromosomes are present in a fetus. Amniotic fluid is obtained for these studies, usually between 16 and 18 weeks of pregnancy. There is a small risk for **miscarriage** with both of these tests. Genetic counseling regarding these procedures involves the careful explanation of benefits and limitations of each testing option. The counselor also tries to explore how patients feel about prenatal testing and the impact of such testing on the pregnancy. Genetic counselors are supportive of any decision a patient makes about whether or not to have prenatal tests performed.

Pediatric genetic counseling

Families or pediatricians seek genetic counseling when a child has features of an inherited condition. Any child who is born with intellectual disabilities, dysmorphic features, or more than one birth defect has an increased chance of having a genetic syndrome.A common type of ID in males for which **genetic testing** is available is **fragile X syndrome**. Genetic testing is also available for many other childhood illnesses such as **hemophilia** and **muscular dystrophy**. Genetic counselors work with medical geneticists to determine if a genetic syndrome is present. This process includes a careful examination of family history, medical history of the child, review of pertinent medical records in the family, a **physical examination** of the child, and sometimes blood work or other diagnostic tests. If a diagnosis is made, then the medical geneticist and genetic counselor review what is known about the

WWW.BOOKBAZ.IR

inheritance of the condition, the natural history of the condition, treatment options, further examinations that may be needed for health problems common in the diagnosed syndrome and resources for helping the family. The genetic counselor also helps the family adjust to the diagnosis by emotional support and counseling. Many families are devastated by receiving a diagnosis, learning of the likely outcome for the child, and by the loss of the hoped-for healthy child. There would also be a discussion about recurrence risks in the family and who else in the family may be at risk.

Adult genetic counseling

Adults seek genetic counseling when a person in the family decides to be tested for a known genetic condition in the family, when an adult begins exhibiting symptoms of an inherited condition or when there is a new diagnosis of someone with an adult onset disorder in the family. In addition, sometimes the birth of a child with obvious features of a genetic disease leads to diagnosis of a parent who is affected more mildly. Genetic counseling for adults may lead to the consideration of presymptomatic genetic testing. Testing a person to determine if they will be symptomatic for a condition before the symptoms occur is an area of controversy. Huntington disease is an example of a genetic disease for which presymptomatic testing is available. Huntington disease is a neurological disease resulting in **dementia**. Onset of the condition is between 30 to 50 years of age. Huntington disease is inherited in an autosomal dominant pattern. If a person has a parent with the disease, their risk of being affected is 50%. Would presymptomatic testing relieve or create **anxiety**? Would a person benefit from removal of doubt about being affected? Would knowing help a person with life planning? Genetic counselors help patients sort through their feelings about such testing and whether or not the results would be helpful to them.

Cancer genetic counseling

A family history of early onset breast, ovarian, or **colon cancer** in multiple generations of a family is a common reason a person would seek a genetic counselor that works with cancer patients. While most cancer is not inherited, there are some families in which a dominant gene is present and causing the disease. The genetic counselor is able to discuss with a patient the chance that the cancer in the family is related to a dominantly inherited gene. The counselor can also discuss the option of testing for the breast and **ovarian cancer** genes, BRCA1 and BRCA2. In some cases the person seeking testing has already had cancer, and in others they have not. Therefore, presymptomatic testing is also an issue in cancer genetics. Emotional support is important for these patients as they have often lost close relatives from cancer and are fearful of their own risks. For families in which a dominant form of cancer is detected through genetic testing, a plan for increased surveillance for the disease can be made.

Pedigree

In all types of genetic counseling, an important aspect of the genetic counseling session is information gathering about family and medical history. Information gathering is performed by drawing a chart called a pedigree. A pedigree is made of symbols and lines that represent the family history. To accurately assess the risk of inherited diseases, information about three generations of the family, including health status and/or cause of death, is usually needed. If the family history is complicated, information from more distant relatives may be helpful, and medical records may be requested for any family members who have had a genetic disorder. Through an examination of the family history a counselor may be able to discuss the probability of future occurrence of genetic disorders.

ETHNICITY. In taking a family history, a genetic counselor asks for the patient's ethnicity or ancestral origin. There are some ethnic groups that have a higher chance of being carriers of specific genetic diseases. For instance, the chance that an African American is a carrier of a gene for **sickle cell disease** is 1 in 10 individuals. People of Jewish ancestry are more likely to be carriers of several conditions including Tay–Sachs disease, Canavan disease and **cystic fibrosis**. People of Mediterranean ancestry are more likely to be carriers of a type of anemia called **thalassemia**. Genetic counselors discuss inheritance patterns of these diseases, carrier risks, and genetic screening or testing options.

CONSANGUNITY. Another question a genetic counselor asks in taking a family history is if the couple is related to one another by blood. The practice of marrying or having children with relatives is infrequent in the United States, but is more common in some countries. When two people are related by blood, there is an increased chance for their children to be affected with conditions inherited in a recessive pattern. In recessive inheritance, each parent of a child affected with a disease carries a single gene for the disease. The child gets two copies, one from each parent, and is affected. People who have a common ancestor are more likely than unrelated people to be

KEY TERMS

Carrier—An individual who possesses a genetic mutation associated with a recessive disorder, but who usually does not display symptoms of that disease. Carriers are able to pass the mutation on to their offspring.

Consanguinity—Related from a common ancestor; blood relative.

Dominant inheritance—A pattern of inheritance in which a trait or disease is conferred by one gene or allele. A parent with a disorder caused by a dominant allele has a 50% chance of passing the trait for disease to their offspring.

Recessive inheritance—A pattern of inheritance where both parents carry the gene responsible for a trait or disease (although they seldom show symptoms). Their offspring will have a 25% chance of having the trait or disease. Recessive inheritance is also responsible for disorders such as hemophilia, where the mother carries the affected gene on the X chromosome and passes it to her son.

carriers of genes for the same recessively inherited genes. Depending on family history and ethnic background, blood tests can be offered to couples to get more information about the chance for these conditions to occur.

EXPOSURES DURING PREGNANCY. During prenatal genetic counseling, the counselor will ask about pregnancy history. If the patient has taken a medication or has had a harmful exposure (like radiation), the genetic counselor can discuss the possibility of harmful effects. Ultrasound is often a useful tool to look for some affects of exposures.

Ethical issues in genetic counseling

Prenatal diagnosis of anomalies or chromosomal abnormalities leads to a decision about whether or not a couple wishes to continue a pregnancy. Some couples chose to continue a pregnancy. Prenatal gives them additional time to emotionally prepare for the birth of the child and to gather resources. Others choose not to continue a pregnancy in which problems have been diagnosed. These couples have unique emotional needs. Often the child is very much a desired addition to the family and parents are devastated that the child is not healthy. Presymptomatic testing for adult onset disorders and cancer raise difficult issues regarding the need to know and the reality of dealing with abnormal results before symptoms. The National Society of Genetic Counselors (NSGC) has established a Code of Ethics to guide genetic counselors in caring for patients. The NSGC Code of Ethics, last updated in 2006, is based on four ethical principles:

- Beneficience is the promotion of personal well-being in others. The genetic counselor is an advocate for the patient.
- Nonmaleficience is the idea of doing no harm to a patient.
- Autonomy is recognizing the value of the individual, the person's abilities and their point of view. Important aspects of autonomy are truthfulness with patients, respecting confidentiality, and practicing informed consent.
- Justice is providing equal care for all, freedom of choice, and providing a high quality of care.

Perhaps the main ethical principle of genetic counseling is the attempt to provide nondirective counseling. This requires a patient–centered approach by providing care focused on the thoughts and feelings of the patient. Five percent of the Human Genome Project budget is assigned to research involving the best way to deal with ethical issues that arise as new genetic tests become available. Genetic counselors can help patients navigate through the unfamiliar territory of genetic testing.

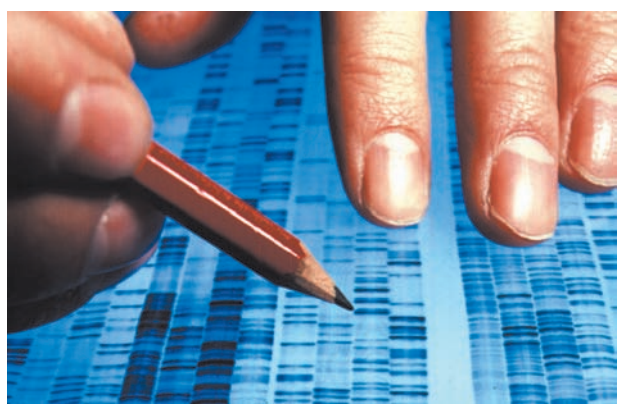
Genetic testing

Definition

A genetic test seeks to identify changes in a person's chromosomes, genes, or proteins that are associated with inherited disorders. Genetic testing is performed to determine if a person has or will develop a certain disease or could pass on a disease to his or her offspring. Genetic tests also determine whether or not couples are at a higher risk than the general population for having a child affected with a genetic disorder.

Purpose

Some families or ethnic groups have a higher incidence of certain diseases than the population as a whole. For example, individuals of Ashkenazi Jewish descent are at higher risk of carrying genes for certain rare conditions, such as **Tay-Sachs disease**, that occur much less frequently in other populations. Before having a child, a couple from such a family or ethnic group may want to know if their child would be at risk of having that disease. Genetic testing for this type of purpose is called genetic screening. Additionally, couples who are having difficulty conceiving a child or who



A scientist examines a DNA sequencing autogradiogram on a light box. *(Photo Researchers, Inc.)*

have suffered multiple miscarriages may be tested to see if a genetic cause can be identified.

During **pregnancy**, a baby's cells can be studied for certain genetic disorders or chromosomal problems such as **Down syndrome**. Chromosome testing is most commonly offered when the mother is 35 years or older at the time of delivery or there is a family medical history of genetic disease. Genetic testing during pregnancy is called prenatal diagnosis.

A genetic disease may be diagnosed at birth by doing a physical evaluation of the baby and observing characteristics of the disorder. Genetic testing can help to confirm any diagnosis made by the physical evaluation. It can also help detect conditions that typically do not manifest until adulthood. In addition, genetic testing is used routinely on all newborns to screen for certain genetic diseases that can affect a newborn baby's health shortly after birth.

Some genetic defects may make a person more susceptible to certain types of cancer, such as **breast cancer**. Testing for these defects can help predict a person's risk. Other types of genetic tests help diagnose and predict and monitor the course of certain kinds of cancer, particularly leukemia and lymphoma.

Description

There are many types of and uses for genetic testing.

Types of genetic testing

GENE TESTS. Gene tests look for signs of a disease by examining DNA taken from a person's blood, body fluids, or tissues. The tests can look for large changes, such as a gene that has a section missing or added, or small changes, such as a missing, added, or altered chemical base within the DNA strand. Other significant changes include genes with too many copies, genes that are too active, genes that are turned off, or genes that are missing.

Various techniques are used for gene tests. Direct DNA sequencing examines the direct base pair sequence of a gene for specific gene mutations. Some genes contain more than 100,000 bases; a mutation of any one base can make the gene nonfunctional and cause disease. The more mutations possible, the less likely it is for a test to detect all of them. This test is usually done on white blood cells from a person's blood, but it can also be performed on other tissues. When the specific genetic mutation is known, it is possible to perform a complete analysis of the genetic code. Another common approach uses chemicals to separate DNA from the rest of the cell. The two strands of DNA are then separated by heating. Special enzymes (called restriction enzymes) are added to the single strands of DNA to cut the strands in specific places. The DNA fragments are then sorted by size through a process called electrophoresis. A special piece of DNA, called a probe, is added to the fragments. The probe is designed to bind to specific mutated portions of the gene. When bound to the probe, the mutated portions appear on x-ray film with a distinct banding pattern.

Another technique is indirect DNA testing. Family linkage studies are done to study a disease when the exact type and location of the genetic alteration is not known, but the general location on the chromosome has been identified. These studies are possible when a chromosome marker associated with a disease has been found. Chromosomes contain certain regions that vary in appearance among individuals. These regions are called polymorphisms and do not cause a genetic disease to occur. If a polymorphism is always present in family members with the same genetic disease, and absent in family members without the disease, it is likely that the gene responsible for the disease is near that polymorphism. The gene mutation can be indirectly detected in family members by looking for the polymorphism. To do so, DNA is isolated from cells in the same way it is for direct DNA mutation analysis. A probe is added to detect the large polymorphism on the chromosome. When bound to the probe, this region will appear on x-ray film with a distinct banding pattern. The pattern of banding of a person being tested for a disease is compared to the pattern from a family member affected by the same disease.

Linkage studies have disadvantages not found in direct DNA mutation analysis. These studies require multiple family members to participate in the testing. If key family members choose not to participate, the incomplete family history may render the results from other members inadequate. The indirect method of detecting a mutated gene also causes more opportunity for error.

CHROMOSOME TESTS. Various genetic syndromes are caused by structural chromosome abnormalities. To analyze a person's chromosomes, his or her cells are allowed to grow and multiply in the laboratory until they reach a certain stage of growth. The length of growing time varies with the type of cells; cells from blood and bone marrow take one to two days, whereas fetal cells from amniotic fluid take up to ten days.

When the cells are ready, they are placed on a microscope slide using a technique to make them burst open, spreading their chromosomes. The slides are stained, and the stain creates a banding pattern unique to each chromosome. Under a microscope, the

WWW.BOOKBAZ.IR

chromosomes are counted, identified, and analyzed based on their size, shape, and stained appearance.

Types of chromosome tests include the karyotype test and the FISH (fluorescence in situ hybridization) test. In a karyotype test, the chromosomes are counted, and a photograph is taken of the chromosomes from one or more cells as seen through the microscope. The chromosomes are then cut out and arranged side-by-side with their partner in ascending numerical order, from largest to smallest. The karyotype is done either manually or using a computer attached to the microscope. The FISH test identifies specific regions on chromosomes using fluorescent DNA probes. FISH analysis can find small pieces of chromosomes that are missing or have extra copies and that can be missed by the karyotype test.

BIOCHEMICAL TESTS. Genes contain instructions for making proteins, and abnormal protein levels can be indicative of a genetic disorder. Biochemical tests look at the level of key proteins. This level can identify genes that are not working normally. These types of tests are typically used for newborn screening. For example, this screening can detect infants who have metabolic conditions such as **phenylketonuria** (PKU).

Applications of genetic testing

NEWBORN SCREENING. In the United States, genetic testing is used most often for newborn screening, a major **public health** program that screens newborns for disorders with long-term health effects. Newborn screening tests infant blood samples for abnormal or missing gene products. Every year, millions of newborn babies have their blood samples tested for potentially serious genetic diseases. Newborn screening programs test for disorders that can cause **infectious disease**, premature death, hearing disorders, or heart problems, as well as other conditions. A method of testing called tandem mass spectrometry allows for screening of up to 30 different metabolic disorders.

CARRIER TESTING. An individual who has a gene associated with a disease but never exhibits any symptoms of the disease is called a carrier. A carrier is a person who is not affected by the mutated gene but can pass the gene to offspring. Genetic tests have been developed to tell prospective parents whether or not they are carriers of certain diseases. If one or both parents are carriers, the risk of passing the disease to a child can be predicted.

To predict the risk, it is necessary to know if the gene in question is autosomal or sex-linked. If the gene is carried on any one of chromosomes 1–22, the resulting disease is called an autosomal disease. If the gene is carried on the X or Y chromosome, it is called a sex-linked disease.

Sex-linked diseases, such as the bleeding condition **hemophilia**, are usually carried on the X chromosome. A woman who carries a disease-associated gene on one of her X chromosomes has a 50% chance of passing that gene to her son. A son who inherits that gene will develop the disease because he does not have another normal copy of the gene on a second X chromosome to compensate for the abnormal copy. A daughter who inherits the disease-associated gene from her mother will be at risk for having a son affected with the disease.

The risk of passing an autosomal disease to a child depends on whether the gene is dominant or recessive. A prospective parent carrying a dominant gene has a 50% chance of passing the gene to a child. A child needs to receive only one copy of the mutated gene to be affected by the disease.

If the gene is recessive, a child needs to receive two copies of the mutated gene—one from each parent—to be affected by the disease. When both parents are carriers, their child has a 25% chance of inheriting two copies of the mutated gene and being affected by the disease, a 50% chance of inheriting one copy of the mutated gene and being a carrier of the disease only, and a 25% chance of inheriting two normal genes. When only one parent is a carrier, a child has a 50% chance of inheriting one mutated gene and being an unaffected carrier of the disease, and a 50% chance of inheriting two normal genes.

Cystic fibrosis, a disease that affects the lungs and pancreas, is the most common autosomal recessive genetic disease found in the Caucasian population. Over 600 mutations of the cystic fibrosis gene have been found, and each of these mutations cause the same disease. Tests that check for the 86 most common mutations in the Caucasian population will detect 90% of carriers for cystic fibrosis. If a person tests negative, it is likely (although not guaranteed) that he or she does not have the gene. Both parents must be carriers of the gene to have a child with cystic fibrosis.

PRESYMPTOMATIC TESTING. Not all genetic diseases show their effects immediately at birth or during childhood, even though the gene mutation is present at birth. If a specific mutated gene responsible for a late-onset disease has been identified, however, a person from an affected family can be tested before symptoms appear.

Huntington's disease is one example of a late-onset autosomal dominant disease. Its symptoms of mental confusion and abnormal body movements do not appear until middle to late adulthood. The chromosome

location of the gene responsible for Huntington's disease was located in 1983 after studying the DNA from a large Venezuelan family affected by the disease. Ten years later the gene was identified. Genetic testing can detect the presence of the expanded base pair sequence responsible for causing this disease; the presence of this expanded sequence indicates that a person will develop the disease.

Another late onset disease, Alzheimer's disease, does not have as well of an understood genetic cause as Huntington's disease. Although many cases appear to be inherited in an autosomal dominant pattern, many cases exist as single incidents in a family. Like Huntington's disease, symptoms of mental deterioration do not appear until late in adulthood. Genetic research has found an association between this disease and genes on four different chromosomes. The validity of looking for these genes in a person without symptoms or without family history of the disease, however, is still being studied.

CANCER SUSCEPTIBILITY TESTING. Cancer can result from an inherited (germline) mutated gene or a gene that mutated sometime during a person's lifetime (acquired mutation). Some genes, called tumor suppressor genes, produce proteins that protect the body from cancer. If one of these genes develops a mutation, it is unable to produce the protective protein. If the second copy of the gene is normal, its action may be sufficient to continue production, but if that gene later also develops a mutation, the person becomes vulnerable to cancer. Other genes, called oncogenes, are involved in the normal growth of cells. A mutation in an oncogene can cause too much growth, which is the beginning of cancer.

Direct DNA tests are currently available to look for gene mutations identified and linked to several kinds of cancer. People with a family history of these cancers are those most likely to be tested. If one of the mutated genes is found, the person is more susceptible to developing the cancer. However, because other genetic and environmental factors are also involved in the development of cancer, the likelihood that the person will develop the cancer is not always known, even with the mutated gene.

Cancer susceptibility tests are most useful when a positive test result can be followed with clear treatment options. In families with **familial polyposis** of the colon, testing a child for a mutated APC gene can reveal whether or not the child needs frequent monitoring for the disease. In families with potentially fatal familial medullary **thyroid cancer** or multiple endocrine neoplasia type 2, finding a mutated RET gene in a child provides the opportunity for that child to have preventive removal of the thyroid gland. In the same way, MSH1 and MSH2 mutations can reveal which members in an affected family are vulnerable to familial colorectal cancer and would benefit from aggressive monitoring.

In 1994, a mutation linked to early onset familial breast and **ovarian cancer** was identified. Women with a mutated form of the BRCA1 gene, located on chromosome 17, have an increased risk of developing breast and ovarian cancer. A second related gene, BRCA2, was later discovered. Located on chromosome 13, it also carries increased risk of breast and ovarian cancer. When a woman is found to have a mutation in one of these genes, the likelihood that she will get breast or ovarian cancer increases, but not to 100%. Other genetic and environmental factors influence the outcome. Both genes are rare in the general population, although they are slightly more common in women of Ashkenazi Jewish descent.

Testing for these genes is most valuable in families where a mutation has already been found. BRCA1 and BRCA2 are large genes; BRCA1 includes 100,000 bases. More than 120 mutations to this gene have been discovered, but a mutation could occur in any one of the bases. Studies show that tests for these genes may miss 30% of existing mutations. The rate of missed mutations, the unknown disease likelihood in spite of a positive result, and the lack of a clear preventive response to a positive result make the value of this test for the general population uncertain.

PRENATAL AND POSTNATAL CHROMOSOME ANALYSIS. Chromosome analysis is performed on fetal cells primarily when the mother is age 35 or older at the time of delivery, has experienced multiple miscarriages, or reports a family history of a genetic abnormality. Prenatal testing is done on the fetal cells by way of **chorionic villus sampling** (from the baby's developing placenta) at 10–12 weeks or with **amniocentesis** (testing the amniotic fluid surrounding the baby) at 16–18 weeks of pregnancy. Cells from amniotic fluid grow for seven to ten days before they are ready to be analyzed. Chorionic villi cells have the potential to grow faster and can be analyzed sooner.

Chromosome analysis using blood cells is done on children who are born with or later develop signs of intellectual disabilities or physical malformations. In the older children, chromosome analysis may be done to investigate developmental delays.

Extra or missing chromosomes cause mental and physical abnormalities. A child born with an extra chromosome 21 (trisomy 21) has Down syndrome.

WWW.BOOKBAZ.IR

An extra chromosome 13 or 18 also produce well-known syndromes. A missing X chromosome causes **Turner syndrome**, and an extra X in a male causes **Klinefelter syndrome**. Other abnormalities are caused by extra or missing pieces of chromosomes. **Fragile X syndrome** is a sex-linked disease that causes **intellectual disability** in males.

Chromosome material may also be rearranged, such as the end of chromosome 1 moving to the end of chromosome 3. This is called a chromosomal translocation. If no material is added or deleted in the exchange, the person may not be affected. Such an exchange, however, can cause **infertility** or abnormalities if passed to children.

Evaluation of a man and woman's infertility or repeated miscarriages includes blood studies of both to check for a chromosome translocation. Many chromosome abnormalities are incompatible with life; babies with these abnormalities often miscarry during the first trimester. Cells from a baby that died before birth can be studied to look for chromosome abnormalities that may have caused the death.

DIAGNOSTIC TESTING. This type of genetic testing is used to confirm a diagnosis when a person has signs or symptoms of a genetic disease. The genetic test used depends on the disease being tested. For example, if a patient has physical features indicative of Down syndrome, a chromosomal test is used. To test for Duchenne **muscular dystrophy**, a gene test is done to look for missing sections in the dystrophin gene.

Chromosome tests are also used to diagnose certain cancers that are associated with changes in chromosomes, particularly leukemia and lymphoma. These changes may include extra or missing complete chromosomes, extra or missing portions of chromosomes, or exchanges of material (translocations) between chromosomes. Studies show that the locations of the chromosome breaks are at locations of tumor suppressor genes or oncogenes.

Chromosome analysis on cells from blood, bone marrow, or solid tumors helps diagnose certain kinds of leukemia and lymphoma and often helps predict how well the person will respond to treatment. After treatment has begun, periodic monitoring of these chromosome changes in the blood and bone marrow gives the physician information as to the effectiveness of the treatment.

A well-known chromosome rearrangement is found in chronic myelogenous leukemia. This leukemia is associated with an exchange of material between chromosomes 9 and 22. The resulting smaller chromosome 22 is called the Philadelphia chromosome.

PHARMACOGENETIC TESTING. Among the latest types of genetic testing is pharmacogenetic testing. Pharmacogenetic testing aims to design individualized drug treatments by analyzing a person's genes to learn how the patient's body will break down certain drugs. For example, a test used in patients who have chronic myelogenous leukemia can show which patients would benefit from a medicine called Gleevec. Another test looks at a liver enzyme called cytochrome P450, which breaks down certain types of drugs. Gene mutations can affect the ability of the body to break down certain drugs and people with a less active form of P450 might absorb excessive levels of a drug. Pharmacogenetic testing seeks to help patients obtain the right amount of a medication.

Methods of genetic testing

Most tests for genetic diseases of children and adults are done on blood. To collect the 5–10 mL of blood needed, a healthcare worker draws blood from a vein in the inner elbow region. Collection of the sample takes only a few minutes.

Prenatal testing is done either on amniotic fluid or a chorionic villus sampling. To collect amniotic fluid, a physician performs a procedure called amniocentesis. An **ultrasound** is done to find the baby's position and an area filled with amniotic fluid. The physician inserts a needle through the woman's skin and the wall of her uterus and withdraws 5–10 mL of amniotic fluid. Placental tissue for chorionic villus sampling is taken through the cervix. Each procedure takes approximately 30 minutes.

Bone marrow is used for chromosome analysis in people with leukemia or lymphoma. After the person is given local **anesthesia**, the physician inserts a needle through the skin and into the bone (usually the sternum or hip bone). One-half to two milliliters (mL) of bone marrow is withdrawn. This procedure takes approximately 30 minutes.

Preparation

A genetic counselor is an individual with a master's degree in genetic counseling. The counselor reviews the person's family history and medical records and the reason for the test. The counselor then explains the likelihood that the test will detect all possible causes of the disease in question (known as the sensitivity of the test), and the likelihood that the disease will develop if the test is positive (known as the positive predictive value of the test).

A variety of genetic tests are now increasingly being offered directly to consumers, usually over the

Internet. Such genetic testing usually involves scraping a few cells from inside the cheek and mailing the sample to a test laboratory, where the test is performed. People considering such genetic tests should discuss the issue with their healthcare provider or a genetic counselor. These tests may not be as reliable as those performed in a clinical setting.

Because genetic testing is not always accurate and because there are privacy concerns for the individual receiving a genetic test, **genetic counseling** should always be performed prior to genetic testing. Learning about the disease in question, the benefits and risks of both positive and negative results, and what treatment choices are available if the result is positive will help prepare the person undergoing testing. During the genetic counseling session, the individual interested in genetic testing will be asked to consider how the test results will affect his or her life, family, and future decisions.

After this discussion, the person should have the opportunity to indicate in writing that he or she gave informed consent to have the test performed, verifying that the counselor provided complete and understandable information.

Aftercare

After blood collection, the person may feel discomfort or bruising at the puncture site or may become dizzy or faint. Pressure to the puncture site until the bleeding stops reduces bruising. Warm packs to the puncture site relieve discomfort.

The chorionic villus sampling, amniocentesis, and bone marrow procedures are all done under a physician's supervision. The person is asked to rest after the procedure and is watched for weakness and signs of bleeding.

Results

A normal result for chromosome analysis is 46, XX or 46, XY. This means there are 46 chromosomes (including two X chromosomes for a female or one X and one Y for a male) with no structural abnormalities. A normal result for a direct DNA mutation analysis or linkage study includes no gene mutations found.

There can be some benefits from genetic testing when the individual tested is not found to carry a genetic mutation. Those who learn with great certainty they are no longer at risk for a genetic disease may choose not to undergo certain prophylactic therapies and may feel less anxious and relieved.

Abnormal results

An abnormal chromosome analysis report will include the total number of chromosomes and will identify the abnormality found. Tests for gene mutations will report the mutations found.

There are many ethical issues to consider with an abnormal prenatal test result. Many of the diseases tested for during a pregnancy cannot be treated or cured. In addition, some diseases tested for during pregnancy may have a late-onset of symptoms or have minimal effects on the affected individual.

Before making decisions based on an abnormal test result, the person should meet again with a genetic counselor to discuss the meaning of the results and learn what options are available, including the risks and benefits of each option.

Risks

Collection of amniotic fluid and chorionic villus sampling carry the risks of **miscarriage**, infection, and bleeding; the risks are higher for chorionic villus sampling. Miscarriage occurs in approximately 0.5% of women after amniocentesis and 1% after chorionic villus sampling. Because of this risk, these prenatal tests are offered to couples but are not required. A woman should tell her physician immediately if she experiences cramping, bleeding, fluid loss, an increased temperature, or a change in the baby's movement following either of these procedures.

After bone marrow collection, the puncture site may become tender and the person's temperature may rise. These are signs of a possible infection.

Genetic testing involves other nonphysical risks. Many people fear the possible loss of privacy about personal health information. Other family members may be affected by the results of a person's genetic test. Privacy of the person tested and the family members affected is a consideration when deciding to have a test and to share the results.

A positive result carries a psychological burden, especially if the test indicates that a person will develop a disease later in life, such as Huntington's disease. The news that a person may be susceptible to a specific kind of cancer may also negatively impact the person's decisions and activities, even when the results encourage positive preventive measures.

A genetic test result may also be inconclusive, meaning no definitive result can be given to the individual or family. This may cause the individual to feel more anxious or frustrated and to experience psychological

WWW.BOOKBAZ.IR

KEY TERMS

Amniocentesis—A procedure for removing amniotic fluid from the womb using a fine needle.

Autosomal disease—A disease caused by a gene mutation located on a chromosome other than a sex chromosome.

Carrier—An individual who possesses an unexpressed abnormal gene of a recessive genetic disorder.

Chorionic villus sampling—A procedure where a needle is inserted into the placenta to withdraw a sample of the placenta's inner wall cells surrounding the fetus.

Chromosomes—Strands of genetic material in a cell. Normal human cells contain 23 chromosome pairs—one in each pair inherited from the mother, and one from the father. Every human cell contains the exact same set of chromosomes.

Dominant—Referring to a genetic trait that is expressed when only one copy of the gene is present.

Gene—A piece of DNA, located on a chromosome, that determines how such traits as blood type are inherited and expressed.

Karyotype—A photomicrograph (picture taken through a microscope) of a person's 46 chromosomes, lined up in 23 pairs, that is used to identify some types of genetic disorders.

Oncogene—A gene that causes normal cell growth, but if mutated or expressed at high levels, encourages normal cells to change into cancerous cells.

Recessive—Referring to a genetic trait expressed only when present on both members of a pair of chromosomes, one inherited from each parent.

Sex-linked genetic disorder—A disease or disorder caused by a gene mutation located on the X (female) or Y (male) chromosome.

Translocation—The rearrangement or exchange of segments of chromosomes that does not alter the total number of chromosomes, but sometimes results in a genetic disorder or disease.

difficulties. The patient should also be aware that the test could miss a mutation or abnormality.

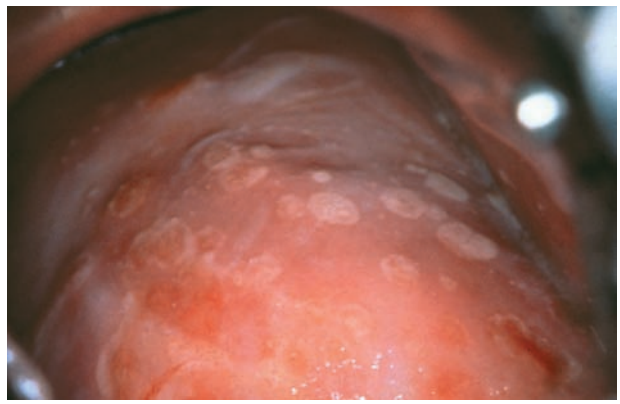
Katherine S. Hunt, MS

Genital herpes

Definition

Genital herpes is a sexually transmitted disease caused by a herpes virus. The disease is characterized by the formation of fluid-filled, painful blisters in the genital area. However, many people who are infected with the virus may not have symptoms and may be unaware they are infected.



Female cervix covered with herpes lesions. *(Photo Researchers, Inc.)*

Demographics

It is estimated that almost 536 million people world–wide between the ages of 15–49 years are living with the herpes simplex type 2 virus (HSV-2). The lowest prevalence of the infection is in Western Europe. Approximately 30 million people in North America are infected with genital herpes. About 17% of the adult population in the United States have antibodies to HSV-2 while almost 60% have antibodies to HSV-1. Newly diagnosed cases of primary genital herpes are increasingly caused by the herpes simplex virus type 1 (HSV-1).

More women (one out of four) than men (one out of eight) have antibodies to the herpes simplex virus. The racial differences for herpes type 2 antibodies are whites, 17.6%; blacks, 45.9%; and Mexican Americans, 22.3%. The occurrence of antibodies to herpes type 1 is higher in blacks.

Interestingly, only 2.6% of adults report that they have had genital herpes.

Description

Genital herpes (herpes genitalis, herpes progenitalis) is characterized by the formation of fluid-filled blisters on the genital organs of men and women. The word "herpes" comes from the Greek adjective *herpestes,* meaning *creeping,* which refers to the serpent–like pattern that the blisters may form. Genital herpes is considered to be a sexually transmitted disease which means that it can be spread from person-to-person by sexual contact. Herpes may be spread by vaginal, anal, or oral sexual activity. In addition,

WWW.BOOKBAZ.IR

A close-up view of a man's penis with a blister (center of image) caused by the herpes simplex virus. *(Custom Medical Stock Photo, Inc.)*

genital herpes may be spread by an infected mother to a baby when the baby passes through the birth canal during the delivery process. It is not spread by objects (such as a toilet seat or doorknob), swimming pools, hot tubs, or through the air.

Genital herpes is a disease resulting from an infection by a herpes simplex virus. There are eight different kinds of human herpes viruses. Only two of these, herpes simplex types 1 and 2, can cause genital herpes. It has been commonly believed that herpes simplex virus type 1 infects above the waist (causing **cold sores**) and herpes simplex virus type 2 infects below the waist (causing genital sores). This generalization is not completely true. Both herpes virus type 1 and type 2 can cause herpes lesions on the lips or genitals, but recurrent cold sores are almost always type 1. The two viruses seem to have evolved to more likely infect at one site or the other, especially with regard to recurrent disease.

Viruses are different from bacteria. While bacteria are independent and can reproduce on their own, viruses cannot reproduce without the help of a cell. Viruses enter human cells and modify them in such as way as to make more virus. A human cell infected with herpes virus releases thousands of new viruses before it is killed by the virus. The cell death and resulting tissue damage causes the actual sores. The highest risk for spreading the virus is the time period beginning with the appearance of blisters and ending with scab formation.

Herpes virus can also infect a cell and instead of making the cell produce new viruses, it hides inside the cell and waits. Herpes virus hides in cells of the nervous system called "neurons." This period is called "latency." A latent virus can remain inside neurons for days, months, or even years. At some future time, the virus "awakens" and causes the cell to produce thousands of new viruses, which causes an active infection. Sometimes an active infection occurs without visible sores. Therefore, an infected person can spread herpes virus to other people even in the absence of sores.

This process of latency and active infection is best understood by considering the genital sore cycle. An active infection is obvious because sores are present. The first infection is called the "primary" infection. This active infection is then controlled by the body's immune system and the sores heal. In between active infections, the virus is latent. At some point in the future, latent viruses become activated and once again cause sores. These episodes are called "recurrent infections" or "outbreaks." Genital sores caused by herpes type 1 recur much less frequently than sores caused by herpes type 2.

Although the factors that trigger latent viruses to activate are not known, several conditions seem to bring on infections. These factors include illness, tiredness, exposure to ultraviolet light (sunlight, **tanning** beds), menstruation, **stress**, **immunosuppression**, sexual intercourse, and genital **trauma**.

In the United States, approximately 22% of pregnant women are infected with HSV-2. Newborn babies who are infected with herpes virus experience a very severe, and possibly fatal disease. This disease is called "neonatal herpes infection."

The risk to the neonate varies depending on the time the mother was infected. If the mother was infected prior to the **pregnancy** or during early pregnancy, the risk for infection to the neonate is about 1%. If a woman becomes infected in the last trimester, the risk of neonatal infection is as high as 30 to 50%. The higher risk for infection in late pregnancy is attributed to an inadequate time to develop the antibodies needed to suppress replication of the virus before labor begins.

In the United States, one in 3,000–5,000 babies born will be infected with the herpes virus. Babies can become infected during passage through the birth canal, but can also become infected during the pregnancy if the mother's membranes rupture early. Doctors will perform a **Cesarean section** on women who go into labor with active genital herpes.

Causes and symptoms

While anyone can be infected by herpes virus, not everyone will show symptoms. Risk factors for genital herpes include: early age at first sexual activity, multiple sexual partners, history of unprotected sexual intercourse, and a medical history of other sexually–transmitted diseases.

Most patients with genital herpes experience a prodrome (symptoms of oncoming disease) of **pain**, burning, **itching**, or tingling at the site where blisters will form. This prodrome stage may last anywhere from a few hours, to one to two days. The herpes infection prodrome can occur for both the primary infection and recurrent infections. The prodrome for recurrent infections may be severe and cause a severe burning or stabbing pain in the genital area, legs, or buttocks.

Primary genital herpes

The first symptoms of herpes usually occur within three to seven days after contact with an infected person, but may take up to two weeks. Symptoms of the primary infection are usually more severe than those of recurrent infections. For up to 70% of patients, the primary infection causes symptoms which affect the whole body (called "constitutional symptoms") including tiredness, **headache**, **fever**, chills, muscle aches, loss of appetite, as well as painful, swollen lymph nodes in the groin. These symptoms are greatest during the first three to four days of the infection and disappear within one week. The primary infection is more severe in women than in men.

Following the prodrome herpes pimples which turn into blisters, which are similar on men and women, begin to appear. First, small red bumps appear. These bumps quickly become fluid-filled blisters. In dry areas, the blisters become filled with pus and take on a white to gray appearance, become covered with a scab, and heal within two to three weeks. In moist areas, the fluid-filled blisters burst and form painful **ulcers** which drain before healing. New blisters may appear over a period of one week or longer and may join together to form very large ulcers. The pain is relieved within two weeks and the blisters and ulcers heal without scarring by two to six weeks.

Women can experience a very severe and painful primary infection. Herpes blisters first appear on the labia majora (outer lips), labia minora (inner lips), and entrance to the vagina. Blisters often appear on the clitoris, at the urinary opening, around the anal opening, and on the buttocks and thighs. In addition, women may get herpes blisters on the lips, breasts, fingers, and eyes. The vagina and cervix are almost always involved, which causes a watery discharge.

KEY TERMS

Groin—The region of the body that lies between the abdomen and the thighs.

Latent virus—An inactive virus which is in a dormant state within a cell. Herpes virus is latent in cells of the nervous system.

Prodrome—Symptoms which warn of the beginning of disease. The herpes prodrome consists of pain, burning, tingling, or itching at a site before blisters are visible.

Recurrence—The return of an active herpes infection following a period of latency.

Ulcer—A painful, pus–draining, depression in the skin caused by an infection.

Other symptoms that occur in women are: painful or difficult urination (83%), swelling of the urinary tube (85%), **meningitis** (36%), and throat infection (13%). Most women develop painful, swollen lymph nodes (lymphadenopathy) in the groin and pelvis. About one in 10 women get a vaginal yeast infection as a complication of the primary herpes infection.

In men, the herpes blisters usually form on the penis but can also appear on the scrotum, thighs, and buttocks. Fewer than half of the men with primary herpes experience constitutional symptoms. Thirty to forty percent of men have a discharge from the urinary tube. Some men develop painful swollen lymph nodes (lymphadenopathy) in the groin and pelvis. Although less frequently than women, men too may experience painful or difficult urination (44%), swelling of the urinary tube (27%), meningitis (13%), and throat infection (7%).

Recurrent genital herpes

Several (five to eight) outbreaks of genital herpes per year occur in 60–90% of those infected with the herpes virus. About 40% of the persons infected with herpes simplex virus type 2 will experience six or more outbreaks each year. Genital herpes recurrences are less severe than the primary infection; however, women still experience more severe symptoms and pain than men. Constitutional symptoms are not usually present. Blisters will appear at the same sites during each outbreak. Usually there are fewer blisters, less pain, and the time period from the beginning of symptoms to healing is shorter than the primary infection. One out of every four women experience painful or

WWW.BOOKBAZ.IR

difficult urination during recurrent infection. Both men and women may develop lymphadenopathy.

Diagnosis

Because genital herpes is so common, it is diagnosed primarily by symptoms. It can be diagnosed and treated by the family doctor or nurse practitioner, dermatologists (doctors who specialize in skin diseases), urologists (doctors who specialize in the urinary tract diseases of men and women and the genital organs of men), gynecologists (doctors who specialize in the diseases of women's genital organs) and **infectious disease** specialists. The diagnosis and treatment of this infectious disease should be covered by most insurance providers.

Examination

The health-care practitioner will examine the patient for typical signs of genital herpes such as shallow, painful ulcers, and swelling in areas where herpes lesions are present. The lymph nodes in the groin will be palpated during the **physical examination**. These lymph nodes are often tender and painful to the touch.

Because newborns who are infected with herpes virus may be born to mothers who have no symptoms of infection it is important to check all newborn babies for symptoms. Any skin sore should be sampled to determine if it is caused by herpes simplex. Babies should be checked for sores in their mouth and for signs of herpes infection in their eyes.

Tests

Laboratory tests may be performed to look for the virus. Because healing sores do not shed much virus, a sample from an open sore would be taken for viral culture. A sterile cotton swab is wiped over open sores and the sample used to infect human cells in culture. Cells which are killed by herpes virus have a certain appearance under microscopic examination. The results of this test are available within two to ten days. Other areas which may be sampled, depending upon the disease symptoms in a particular patient, include the urinary tract, vagina, cervix, throat, eye tissues, and cerebrospinal fluid.

Direct staining and microscopic examination of the lesion sample may also be used. A blood test may be performed to see if the patient has antibodies to herpes virus. The results of blood testing are available within one day. The disadvantage of this blood test is that it usually does not distinguish between herpes type 1 and 2, and only determines that the patient has had a herpes infection at some point in his or her life. Therefore, the viral culture test must be performed to be absolutely certain that the sores are caused by herpes virus.

Because genital sores can be symptoms of many other diseases, the doctor must determine the exact cause of the sores. The above mentioned tests are performed to determine that herpes virus is causing the genital sores. Other diseases which may cause genital sores are **syphilis**, **chancroid**, **lymphogranuloma venereum**, **granuloma inguinale**, herpes zoster, erythema multiform, Behçet's syndrome, inflammatory bowel disease, **contact dermatitis**, **candidiasis**, and **impetigo**.

Treatment

There is no cure for herpes virus infections. There are **antiviral drugs** available which have some effect in lessening the symptoms and decreasing the length of herpes outbreaks. There is evidence that some may also prevent future outbreaks. These antiviral drugs work by interfering with the replication of the virus and are most effective when taken as early in the infection process as possible. For the best results, drug treatment should begin during the prodrome stage before blisters are visible. Depending on the length of the outbreak, drug treatment can continue for up to 10 days.

Drugs

Antiviral agents such as acyclovir (Zovirax), famciclovir (Famvir), and valacyclovir (Valtrex) appear to be equally effective as treatment agents for primary genital HSV infection although treatment with acyclovir is typically less expensive. The drugs, which are most frequently given orally to treat uncomplicated cases of genital herpes, should be started within 72 hours of the appearance of lesions to be most effective. Beginning treatment within this time frame appears to decrease the duration of the outbreak and often lessens the severity of the infection.

Currently, recommended doses and treatment schedules for these drugs are:

- acyclovir, 400 mg by mouth three times per day
- famciclovir, 250 mg by mouth three times per day
- valacyclovir, 1000 mg by mouth two times per day

Duration of treatment is usually seven to ten days.

Treatment of recurrent episodes

Treatment strategies for recurrent episodes of genital herpes depend on the frequency of the episodes

and the severity of the outbreaks among other considerations. These strategies include:

- No treatment may be recommended for individuals who experience infrequent outbreaks and/or minimal symptoms with outbreaks.
- Chronic suppressive therapy is recommended for people with very frequent recurrences and for individuals who are HSV-seropositive with uninfected sexual partners. This strategy involves daily antiviral therapy.
- Episodic therapy may be used by individuals to treat outbreaks of the infection as they occur. Patients should be counseled to begin treatment with antivirals when prodromal symptoms (tingling, itching, burning, pain) begin and before herpes pimples and blisters occur.

Treatment for complicated genital herpes infection

Complicated genital herpes includes those cases in which there is involvement of the central nervous system such as in cases of aseptic meningitis, encephalitis, or tranverse myelitis associated with the herpes infection. Other complications can include hepatitis, pneumonitis, and HSV infection which is wide–spread. The Centers for Disease Control (CDC) recommends treatment with intravenous acyclovir at a dose of 5 to 10 mg/kg every eight hours for two to seven days or longer as the treatment for complicated cases of genital herpes. Treatment is continued until clinical improvement is noted. Following conclusion of intravenous antiviral therapy, the patient is started on oral antiviral therapy for at least an additional 10 days. Some patients may require longer duration of treatment.

Neonatal herpes

Newborn babies with herpes virus infections are treated with intravenous acyclovir. The duration of treatment, which may last 21 days or longer, depends on the extent of the infection and on the baby's response to therapy. Treatment with antivirals and other supportive measures has greatly reduced deaths and increased the number of babies who appear normal at one year of age. However, because neonatal herpes infection is so serious, even with treatment babies may not survive, or may suffer nervous system damage.

Alternatives

An imbalance in the amino acids lysine and arginine is thought to be one contributing factor in herpes virus outbreaks. A ratio of lysine to arginine that is in balance (that is more lysine than arginine is present) seems to help the immune system work optimally. Thus, a diet that is rich in lysine may help prevent recurrences of genital herpes. Foods that contain high levels of lysine include most vegetables, legumes, fish, turkey, beef, lamb, cheese, and chicken. Patients may take 500 mg of lysine daily and increase to 1,000 mg three times a day during an outbreak. Intake of the amino acid arginine should be reduced. Foods rich in arginine that should be avoided are chocolate, peanuts, almonds, and other nuts and seeds.

Clinical experience indicates a connection between high stress and herpes outbreaks. Some patients respond well to **stress reduction** and relaxation techniques. **Acupressure** and massage may relieve tiredness and stress. **Meditation**, **yoga**, tai chi, and **hypnotherapy** can also help relieve stress and promote relaxation.

Some herbs, including **echinacea** (*Echinacea* spp.) and garlic (*Allium sativum*), are believed to strengthen the body's defenses against viral infections. Red marine algae (family Dumontiaceae), both taken internally and applied topically, is thought to be effective in treating herpes type I and type II infections. Other topical treatments may be helpful in inhibiting the growth of the herpes virus, in minimizing the damage it causes, or in helping the sores heal. Zinc sulphate ointment seems to help sores heal and to fight recurrence. Lithium succinate ointment may interfere with viral replication. An ointment made with glycyrrhizinic acid, a component of licorice (*Glycyrrhiza glabra*), seems to inactivate the virus. Topical applications of **vitamin E** or tea tree oil (*Melaleuca* spp.) help dry up herpes sores. Results of one study indicated that using an ointment containing propolis, a waxy substance made by bees, helped in healing herpes lesions. Individuals using the ointment four times a day for 10 days reported improvement in the lesions. Other research seems to indicate that the herb Prunella vulgaris and an edible mushroom, Rozites caperata (also known as gypsy mushroom) contain chemicals that may be helpful in fighting the effects of HSV-1 and HSV-2. Specific combinations of homeopathic remedies may also be helpful treatments for genital herpes.

There are several things that a patient may do to lessen the pain of genital sores. Over-the-counter pain relievers such as **aspirin**, **acetaminophen**, or ibuprofen may help to reduce the pain associated with a herpes outbreak. Wearing loose fitting clothing and cotton underwear is helpful. Removing clothing or wearing loose pajamas while at home may

WWW.BOOKBAZ.IR

reduce pain. Soaking in a tub of warm water and using a blow dryer on the "cool" setting to dry the infected area is helpful however, most clinicians recommend keeping infected areas dry most of the time. Putting an ice pack on the affected area for 10 minutes, followed by five minutes off and then repeating this procedure may relieve pain. Application of a baking soda compress to sores may be soothing.

Prognosis

Although physically and emotionally painful, genital herpes is usually not a serious disease. The primary infection can be severe and may require hospitalization for treatment. Complications of the primary infection may involve the cervix, urinary system, anal opening, and the nervous system. Persons who have a decreased ability to produce an immune response to infection (called "immunocompromised") due to disease or medication are at risk for a very severe, and possibly fatal, herpes infection. Even with antiviral treatment, neonatal herpes infections can be fatal or cause permanent nervous system damage.

Prevention

The only way to prevent genital herpes is to avoid contact with infected persons. This is not an easy solution because many people are not aware that they are infected and can easily spread the virus to others. Avoid all sexual contact with an infected person during a herpes outbreak. Because herpes virus can be spread at any time, condom use is recommended to prevent the spread of virus to uninfected partners. At this time, there is no vaccine available to prevent genital herpes.

Genital warts

Definition

Genital **warts**, which are also called condylomata acuminata or venereal warts, are growths in the genital area caused by a sexually transmitted papillomavirus. A papillomavirus is a virus that produces papillomas, or benign growths on the skin and mucous membranes.

Description

Genital warts are the most common sexually transmitted disease (STD) in the general population. It is estimated that 1% of sexually active people between the ages of 18 and 45 have genital warts; however, polymerase chain reaction (PCR) testing indicates that as many as 40% of sexually active adults carry the **human papillomavirus** (HPV) that causes genital warts.

Genital warts vary somewhat in appearance. They may be either flat or resemble raspberries or cauliflower in appearance. The warts begin as small red or

Man with genital warts. *(Custom Medical Stock Photo, Inc.)*

KEY TERMS

Condylomata acuminata—Another name for genital warts.

Papilloma—A benign growth on the skin or mucous membrane. Viruses that cause these growths are called human papillomaviruses (HPVs).

Podophyllum resin—A medication derived from the May apple or mandrake and used to treat genital warts.

pink growths and grow as large as four inches across, interfering with intercourse and **childbirth**. The warts grow in the moist tissues of the genital areas. In women, they occur on the external genitals and on the walls of the vagina and cervix; in men, they develop in the urethra and on the shaft of the penis. The warts then spread to the area behind the genitals surrounding the anus.

Risk factors for genital warts include:

- multiple sexual partners
- infection with another STD
- pregnancy
- anal intercourse
- poor personal hygiene
- heavy perspiration

Causes and symptoms

There are about 80 types of human papillomavirus. Genital warts are caused by HPV types 1, 2, 6, 11, 16, and 18. HPV is transmitted by sexual contact. The incubation period varies from one to six months.

The symptoms include bleeding, **pain**, and odor as well as the visible warts.

Diagnosis

The diagnosis is usually made by examining scrapings from the warts under a darkfield microscope. If the warts are caused by HPV, they will turn white when a 5% solution of white vinegar is added. If the warts reappear, the doctor may order a biopsy to rule out cancer.

Treatment

No treatment for genital warts is completely effective because therapy depends on destroying skin infected by the virus. There are no drugs that will kill the virus directly.

Medications

Genital warts were treated until recently with applications of podophyllum resin, a corrosive substance that cannot be given to pregnant patients. A milder form of podophyllum, podofilox (Condylox), has been introduced. Women are also treated with 5-fluorouracil cream, bichloroacetic acid, or trichloroacetic acid. All of these substances irritate the skin and require weeks of treatment.

Genital warts can also be treated with injections of interferon. Interferon works best in combination with podofilox applications.

Surgery

Surgery may be necessary to remove warts blocking the patient's vagina, urethra, or anus. Surgical techniques include the use of liquid nitrogen, electrosurgery, and **laser surgery**.

Prognosis

Genital warts are benign growths and are not cancerous by themselves. Repeated HPV infection in women, however, appears to increase the risk of later **cervical cancer**. Women infected with HPV types 16 and 18 should have yearly cervical smears. Recurrence is common with all present methods of treatment—including surgery—because HPV can remain latent in apparently normal surrounding skin.

Prevention

The only reliable method of prevention is sexual abstinence. The use of **condoms** minimizes but does not eliminate the risk of HPV transmission. The patient's sexual contacts should be notified and examined.

Germ cell tumors

Definition

Germ cell tumors (GCTs) are solid tumors which are diagnosed in children, adolescents, and less frequently, in adults. The term germ cell tumor alludes to the term "germinate" rather than to the term "germ" as it relates to bacterial or other related organisms that are capable of causing disease. These tumors arise from germ cells that develop into reproductive tissue such as testicular and ovarian cells. GCTs can be benign tumors or malignant (cancerous) tumors.

Demographics

The incidence of GCTs appears to be increasing. Malignant germ cell tumors account for about 3% of all cases of cancer occurring in children and adolescents prior to age 20 years. Malignant GCTs are more commonly diagnosed in adolescents between the ages of 15 and 19 years and account for about 14% of all cancers which occur in this age group.

Description

GCTs appear to arise from primitive germs cells. During embryo development, these germ cells migrate from the yolk sac down the midline of the body to the pelvis and eventually to the gonads, or reproductive organs. During fetal development, some of the cells may migrate to abnormal sites other than the gonads, however. Therefore, GCTs are classified as gonadal GCTs or extragonadal GCTs, meaning they occur in tissues that are not reproductive tissue. About 90% of GCTs are gonadal in origin.

Malignant GCTs can be further histologically classified according to the origin of the tumor. In young children, GCTs are classified as yolk sac tumors, which can arise from extragonadal, ovarian, or testicular tissue, or dysgerminoma, which arises from ovarian tissue and is rarely diagnosed in young children. In adolescents and in young adults, malignant GCTs can be classified as follows:

- seminoma–germinomas which arise from testicular tissue
- dysgerminoma–germinomas which arise from ovarian tissue
- germinoma–extagonadal origin
- yolk sac tumor–extragonadal, ovarian and testicular origin; also termed endodermal sinus tumors
- choriocarcinoma–extragonadal, ovarian, and testicular origin; a rare tumor type
- embryonal carcinoma–arises from testicular tissue
- mixed germ cell tumors–arises from extragonadal and ovarian tissue

Testicular and mediastinal seminomas are most likely to be diagnosed in adolescent and young adult males while ovarian dysgerminomas are more likely to be diagnosed in adolescent and young adult females. Most children who are diagnosed with a malignant GCT are most likely to have a yolk sac component to their tumors.

Some of the malignant GSTs secrete abnormal proteins such as alpha–fetaprotein (AFP) and beta–human chorionic gonadotropin (b–HCG) which are considered to be **tumor markers**. For example, yolk sac tumors secrete AFP while germinomas (such as seminoma and dysgerminoma) and choriocarcinomas produce b–HCG. Serum levels of these tumor markers can be monitored during treatment to determine the response of the tumor to the treatment.

Risk factors

Specific risk factors related to the development of GCTs have not been identified. However, patients diagnosed with certain genetic or hereditary syndromes or disorders appear to be at higher risk for the development of some types of GCTs. For example, individuals with **Klinefelter syndrome** appear to be at increased risk for the development of extragonadal GCT and patients with Swyer syndrome may be at increased risk for the development of germinomas.

Causes and symptoms

The specific cause of most cases of GCTs is unknown at this time. Some individuals with certain genetic or hereditary syndromes and disorders appear to be at higher risk for the development of some types of GCTs. In addition, several chromosomal abnormalities are being studied to determine their exact role in causing GCTs.

Symptoms of GCTs are linked to the size and location of the tumor. Symptoms may include:

- a swelling or mass of tissue that can be palpated
- abnormal shape or size of the testicle
- excessive hair growth
- early puberty
- hormonal abnormalities such as diabetes
- headache
- weakness in the lower extremities
- constipation

KEY TERMS

Embryo—The human organism in the earliest stages of development.

Extragonadal—Occurring outside of the gonads or outside of the reproductive organs.

Gonads—The reproductive organs; testes in males and ovaries in females.

Histology—The study of the structure, composition, and function of tissues of organs.

Tumor marker—A biochemical substance produced and released or secreted by a tumor.

Yolk sac—A sac made of membranous tissue that is attached to the embryo and provides nutrition to the embryo.

Diagnosis

Examination

A complete history and **physical examination** will be conducted. The suspected tumor mass will be examined and palpated. A focused assessment and examination will be conducted based on the location of the suspected tumor.

Tests

Levels of tumor markers such as AFP and b–HCG should be assessed prior to surgical intervention. Lactate dehydrogenase levels will also be determined. Tests which should be conducted prior to **chemotherapy** administration include a **complete blood count** (CBC) with differential and **platelet count**, tests to determine baseline kidney function such as the glomerular filtration rate and creatinine clearance rate, uric acid levels, **liver function tests**, and electrolyte levels as well as the levels of **calcium** and magnesium in the body.

Radiologic procedures which may be utilized include chest xray and magnetic imaging scanning (MRI) to evaluate for metastasis to the lungs, computed tomography (CT) and/or MRI scanning of the abdomen and/or pelvis if tumor is suspected in those locations, and bone scans to further determine extent of metastasis. Other tests which may be done, depending on the location of the tumor, include CT or MRI scans of the brain, ultrasounds of the abdomen and pelvis, testicular ultrasounds, and **positron emission tomography** (PET) scans to detect relapse of tumor. In addition, **pulmonary function tests** may be done to establish baseline pulmonary function prior to the start of chemotherapy administration.

Treatment

Treatment for these relatively rare types of cancer should be conducted at pediatric cancer centers experienced in treating GCTs. Factors which play a role in determining optimum treatment for GCTs include the histology of the tumor, tumor stage, the location of the primary tumor and the patient's age. Clinicians treating these children and adolescents will attempt to maximize the potential for survival while attempting to minimize the risk for adverse long–term side effects such as the development of second cancers, and other serious physical and cognitive impairments.

Currently, multimodality therapy is utilized including surgery and administration of chemotherapy. Based on the factors described above, treatment options may include:

- surgical removal of the tumor followed by strict surveillance for tumor relapse
- biopsy of the tumor to obtain a definitive diagnosis, followed by preoperative chemotherapy administration which includes a platinum–based chemotherapy drug, followed by surgical removal of all remaining tumor
- surgical removal of the tumor followed by platinum–based chemotherapy administration.

Currently, the standard chemotherapy regimen for children and adults diagnosed with malignant nonseminomatous GCTs includes the drugs cisplatin, etoposide and bleomycin. However, children are given fewer doses of bleomycin than adults.

There are different treatment options for malignant testicular GCTs in boys than for adolescents and young adult males which vary by stage of disease at the time of diagnosis and age of the patient. Treatment options for childhood ovarian GCT includes a multimodality approach which may utilize surgery, observation, and chemotherapy. Current standard treatment options for childhood malignant extragonadal GCTs varies by patient age, tumor location, tumor histology, and stage at time of diagnosis and may include surgery and chemotherapy administration.

Prognosis

The 5-year survival rate for gonadal GCTs increased from 89% to 98% in children younger than age 15 years between 1975 and 2002 according to the National Cancer Institute. The 5-year survival rate for

WWW.BOOKBAZ.IR

adolescents diagnosed with gonadal GCTs between the ages of 15 and 19 years increased from 70% to 95% during that same time period.

The 5-year survival rate for extragonadal GCTs increased from 42% to 83% in children younger than age 15 years between 1979 and 2002. The 5-year survival rate for adolescents between the ages of 15 and 19 years increased from 80% to 95% during that same time period.

Prevention

As the cause of most cases of childhood GCTs is not currently known, there are no ways to prevent development of GCTs. Children diagnosed with specific congenital or hereditary syndromes or disorders which increase their risk of developing GCTs should be screened for GCTs.

German measles *see* **Rubella**

Gerontology

Definition

Gerontology is the study or **aging** and problems that affect people as they age.

Description

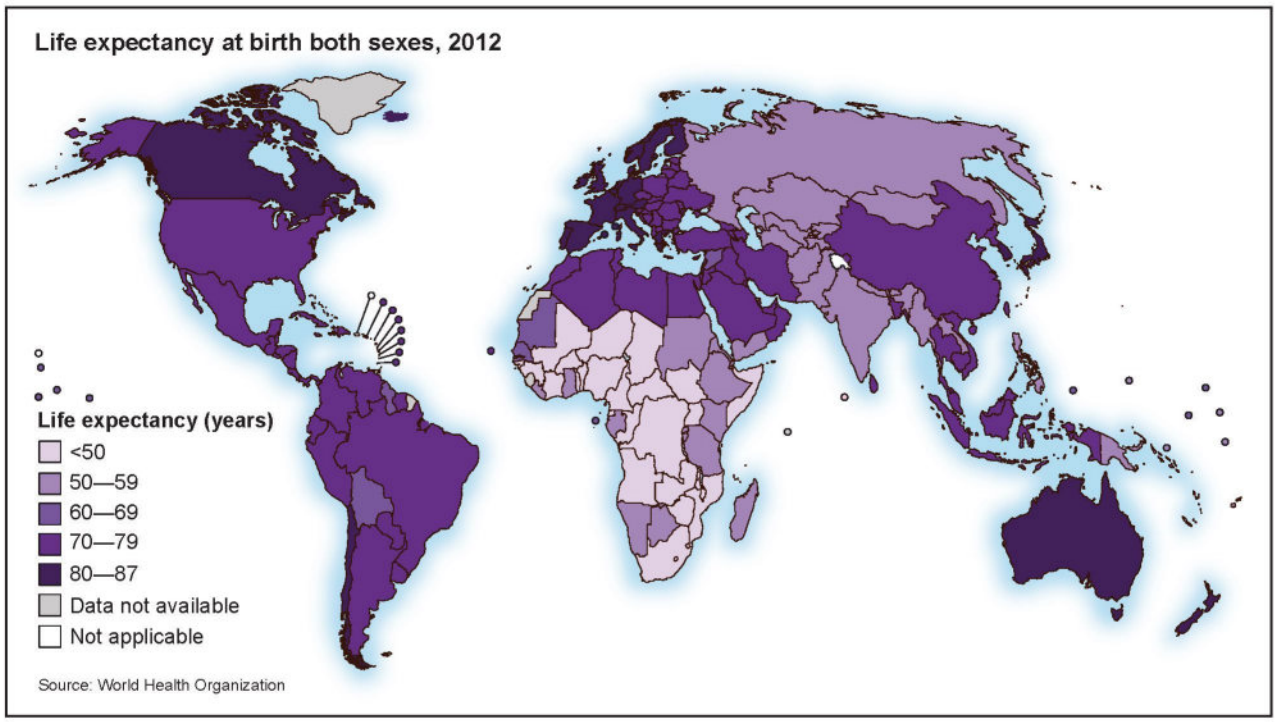
As medicine has advanced and people have begun to live longer lives, the field of gerontology has evolved to thoroughly study the physical, social, psychological, and **public health** aspects of older people. The area of science contributes to important research, decisions, and policies in government, healthcare, business and sociology.

Gerontology is different from geriatrics. Gerontology is a scientific discipline that studies the aging and ageism as a whole to learn more about typical changes in the body and mind that occur as people live longer, but also to understand how an increase in the number of elderly people in a population affects society or economics. Geriatrics is a medical specialty more concerned with caring for older people, treating them for diseases or helping them stay well as they age.

Origins

In ancient times, literature often referred to the elderly as those who held knowledge and wisdom. Yet, growing old has also been associated with a sadness as one faces the approaching physical and mental decline. Nobel laureate Elie Metchnikoff questioned whether people had to decline as they aged, or whether studying the aging process could improve quality of life for elderly people. Metchnikoff expressed these thoughts in the early 1900s, and is considered the pioneer of modern gerontology.

It was Metchnikoff who suggested that gerontology cover not just medicine, but many disciplines, in helping the aged lead more satisfying and productive



(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

lives. Research followed, along with several theories related to aging. In 1945, the Gerontological Society of America (GSA) was formed. The society is the oldest organization in the United States that represents several disciplines devoted to research and education about aging.

Demographics

According to the World Health Organization (WHO), nearly all of the world's countries are experiencing population aging, or a shift toward a higher proportion of elderly people and a lower number of children. The percentage of people older than age 60 increased from 9.2% in 1990 to 11.7% in 2013. By 2050, WHO estimates the figure to be at more than 20%, for a total of 2 billion people.

In the United States, more than 13% of the population is elderly. There were more than 43 million people older than age 65 in 2012, an increase of 21% since 2002. There are nearly 6 million more older women than men. The population of very old people, those age 85 and older, also has increased dramatically, to 5.9 million in 2012. This population is expected to reach about 14 million by the year 2040.

Because of the many different disciplines involved, it is difficult to measure exactly how many people work in the field of gerontology. The GSA now has more than 5,500 members. More than 500 colleges and universities have various credit programs in aging. People training in gerontology may receive degrees from the associate through postdoctoral, or fellowship, level. People who work in gerontology may be employed at community organizations, in healthcare facilities, at retirement communities, in research facilities, or by local, state, or federal government agencies.

Purpose

Organizations such as GSA are based on the idea that when professionals from many different areas of study or practice, such as doctors, nurses, scientists, psychologists, and biologists, share information, they can better understand and promote healthy aging. In most industrialized nations around the world, the number of elderly people still living has increased in relation to the general population. Nations and communities face important decisions about policies and services to help care for elderly people who have medical, social, and economic needs. Improved services and approaches also help families who help care for aging relatives. The elderly themselves want to remain physically and financially independent as long as possible.

The GSA publishes a scholarly journal dedicated to sharing scientific research on aging, along with a journal

WWW.BOOKBAZ.IR

KEY TERMS

Geriatrics—A medical specialty that focuses on treating or preventing diseases in older people.

Gerontology—The scientific field that focuses on studying the physical, mental, and social health of aging.

that focuses on biological and medical sciences, and one that focuses on psychological and social sciences.

As societies age, changes in living and family arrangements occur. Shifts in ages of populations can even affect a country's economy or labor force. For example, an increasingly growing and aging Baby Boomer population in the United States is increasing the need for home health workers and people in many other healthcare professions. At the same time, more older people may rely on Social Security wages and Medicare or other publicly funded programs. Learning how to keep older people healthy improves the quality of life of an important group of citizens and can contribute to lower health costs.

Much of the research and work done by professionals in the field of gerontology is aimed at reducing disparities between elderly people in a population and the rest of the population. This means identifying causes of lower income, poor living or health conditions, and other issues facing older people in a particular community or setting, and determining how to improved the conditions. People who perform research in gerontology may receive grants, publish their results, or help put results into action.

Gestalt therapy

Definition

Gestalt therapy is a humanistic therapy technique that focuses on gaining an awareness of emotions and behaviors in the present rather than in the past. The therapist does not interpret experiences for the patient. Instead, the therapist and patient work together to help the patient understand him/herself. This type of therapy focuses on experiencing the present situation rather than talking about what occurred in the past. Patients are encouraged to become aware of immediate needs, meet them, and let them recede into the background. The well-adjusted person is seen as someone who has a constant flow of needs and is able to satisfy those needs.

Purpose

In Gestalt therapy (from the German word meaning *form*), the major goal is self-awareness. Patients work on uncovering and resolving interpersonal issues during therapy. Unresolved issues are unable to fade into the background of consciousness because the needs they represent are never met. In Gestalt therapy, the goal is to discover people connected with a patient's unresolved issues and try to engage those people (or images of those people) in interactions that can lead to a resolution. Gestalt therapy is most useful for patients open to working on self-awareness.

Precautions

The choice of a therapist is crucial. Some people who call themselves "therapists" have limited training in Gestalt therapy. It is important that the therapist be a licensed mental health professional. Additionally, some individuals may not be able to tolerate the intensity of this type of therapy.

Description

Gestalt therapy has developed into a form of therapy that emphasizes medium to large groups, although many Gestalt techniques can be used in one-on-one therapy. Gestalt therapy probably has a greater range of formats than any other therapy technique. It is practiced in individual, couples, and family therapies, as well as in therapy with children.

Ideally, the patient identifies current sensations and emotions, particularly ones that are painful or disruptive. Patients are confronted with their unconscious feelings and needs, and are assisted to accept and assert those repressed parts of themselves.

The most powerful techniques involve role-playing. For example, the patient talks to an empty chair as they imagine that a person associated with an unresolved issue is sitting in the chair. As the patient talks to the "person" in the chair, the patient imagines that the person responds to the expressed feelings. Although this technique may sound artificial and might make some people feel self-conscious, it can be a powerful way to approach buried feelings and gain new insight into them.

Sometimes patients use battacca bats, padded sticks that can be used to hit chairs or sofas. Using a battacca bat can help a patient safely express anger. A patient may also experience a Gestalt therapy marathon, where the participants and one or more facilitators have nonstop **group therapy** over a weekend. The effects of the intense emotion and the lack of sleep can eliminate many psychological defenses and allow significant progress to be made in a short time. This is true only if the patient has adequate psychological strength for a marathon and is carefully monitored by the therapist.

Preparation

Gestalt therapy begins with the first contact. There is no separate diagnostic or assessment period. Instead, assessment and screening are done as part of the ongoing relationship between patient and therapist. This assessment includes determining the patient's willingness and support for work using Gestalt methods, as well as determining the compatibility between the patient and the therapist. Unfortunately, some "encounter groups" led by poorly trained individuals do not provide adequate pre-therapy screening and assessment.

Aftercare

Sessions are usually held once a week. Frequency of sessions held is based on how long the patient can go between sessions without losing the momentum from the previous session. Patients and therapists discuss when to start sessions, when to stop sessions, and what kind of activities to use during a session. However, the patient is encouraged and required to make choices.

Results

Scientific documentation on the effectiveness of Gestalt therapy is limited. Evidence suggests that this type of therapy may not be reliably effective.

Abnormal

This approach can be anti-intellectual and can discount thoughts, thought patterns, and beliefs. In the hands of an ineffective therapist, Gestalt procedures can become a series of mechanical exercises, allowing the therapist as a person to stay hidden. Moreover, there is a potential for the therapist to manipulate the patient with powerful techniques, especially in therapy marathons where **fatigue** may make a patient vulnerable.

Risks

Disturbed people with severe mental illness may not be suitable candidates for Gestalt therapy. Facilities that provide Gestalt therapy and train Gestalt therapists vary. Since there are no national standards for these Gestalt facilities, there are no set national standards for Gestalt therapy or Gestalt therapists.

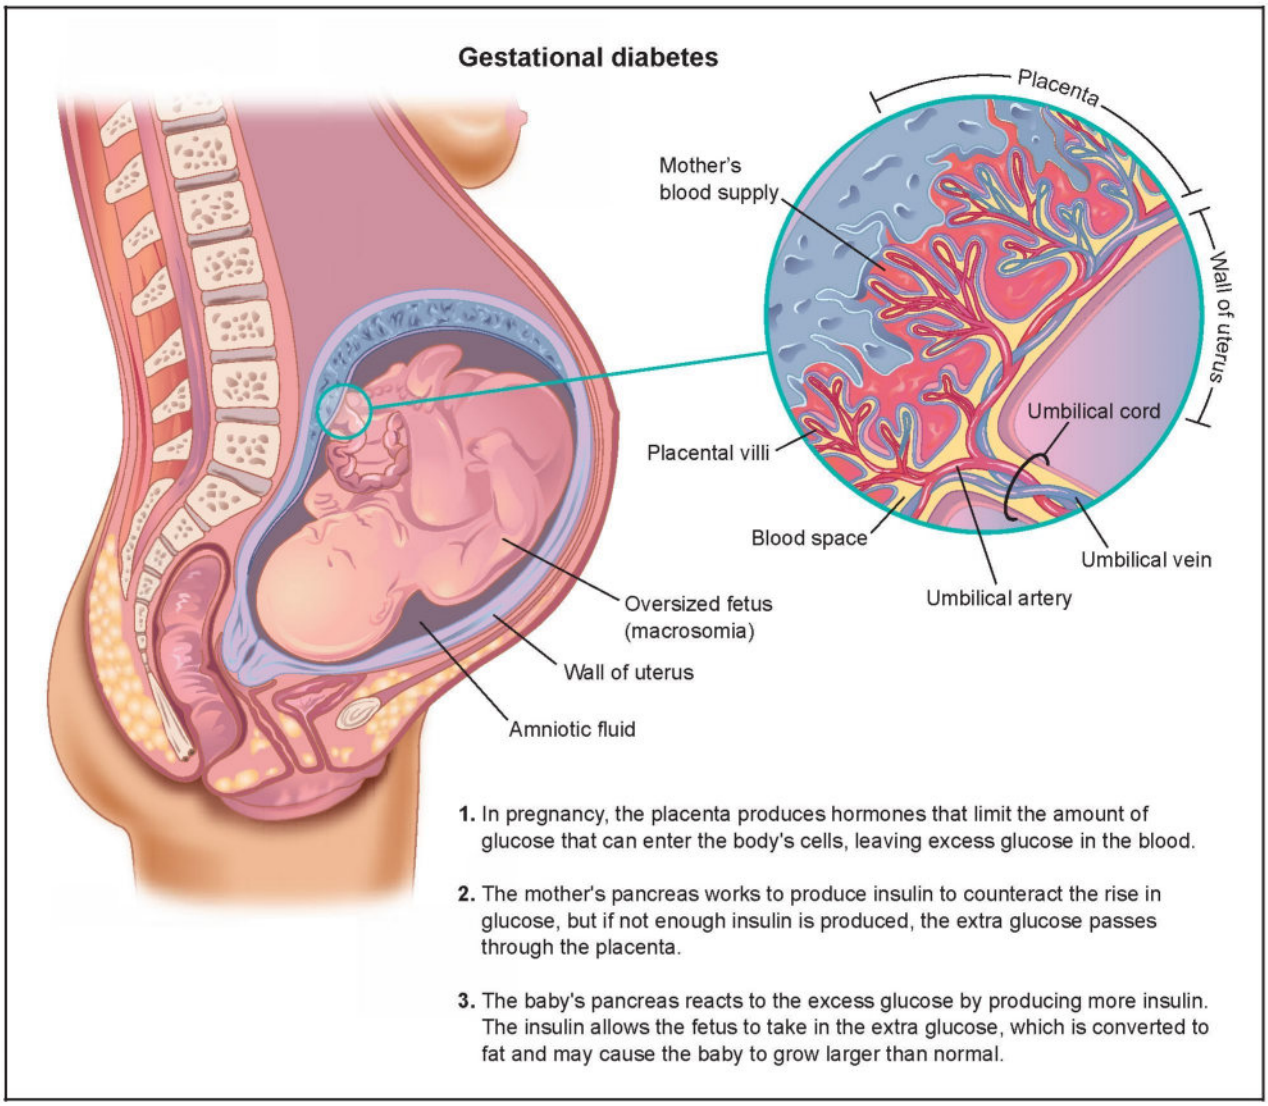
David James Doermann

Gestational diabetes

Definition

Gestational diabetes is an abnormal increase blood sugar (glucose) levels that occurs during **pregnancy** in some women. Unlike other types of diabetes, gestational diabetes first appears during pregnancy and then disappears after the woman gives birth.

WWW.BOOKBAZ.IR



(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

Demographics

Studies have found that in the United States between 3% and 10% of women experience diabetes during pregnancy. Ninety percent of these women develop gestational diabetes, about 8% have pre-existing type 2 (insulin resistant) diabetes, while about 1% have pre-existing type 1 (insulin deficiency) diabetes.

Race and ethnicity strongly affect the rate of development of gestational diabetes. Only about 1.4–2% of Caucasian women develop gestational diabetes, while as many as 15% of Native American women from tribes in the Southwest United States develop the disorder. Between 5% and 8% of Hispanic Americans, African Americans, and Asian Americans develop gestational diabetes. If a woman experiences gestational diabetes, the chance of her developing it again in future pregnancies is as high as 68%.

Description

Carbohydrates (sugars and starches) found in foods such as sweets, potatoes, pasta, and breads, are broken down during digestion into glucose, a simple sugar that circulates in the blood and is used by cells for energy. The level of glucose changes depending on what food and how much of it a person eats. The level usually is highest about two hours after a meal.

However, in order for the body to remain healthy, blood glucose levels must stay stable with certain narrow limits. In healthy people, the hormone insulin regulates the blood glucose level by controlling how much glucose enters cells. Once in cells, glucose either is used to meet the immediate energy needs of the cell or stored in liver, muscle, or fat cells for later release when blood glucose levels are low. In people with diabetes, this regulatory mechanism does not function correctly, and glucose builds up in the blood, a condition called hyperglycemia.

There are three types of diabetes. In type 1 diabetes, the pancreas, a digestive system organ, does not make any insulin or does not make enough insulin to properly regulate blood glucose levels. People with type 1 diabetes must control their blood glucose through diet, **exercise**, and most importantly, through the regular injection of synthetic or animal insulin.

In type 2 diabetes, the pancreas makes enough insulin, but cells become unresponsive to it, a condition called **insulin resistance**. As a result, adequate amounts of glucose cannot enter these cells, and glucose builds up in the blood. Many people with type 2 diabetes can control their blood glucose level through diet and exercise. Others must take supplemental insulin either by mouth (orally) or by injection.

In gestational diabetes, the pancreas makes insulin, but the placenta, which allows the fetus to obtain nourishment, produces hormones (e.g., estrogens, progesterone, and chorionic somatomammotropin) that increase the insulin resistance of cells. These hormones are at their highest levels during the third trimester of pregnancy. Their presence reduces the amount of glucose that can enter cells, so that more remains in the blood and hyperglycemia occurs. Most pregnant women do not develop gestational diabetes because the pancreas produces additional quantities of insulin (as much as 50% more than normal in the third trimester) in order to compensate for insulin resistance caused by pregnancy hormones. However, when a woman's pancreas cannot produce enough extra insulin, blood levels of glucose stay abnormally high, and the woman develops gestational diabetes.

Risk factors

Women at risk for gestational diabetes include those who:

- are overweight
- have a family history of diabetes
- have previously given birth to a very large, heavy baby
- have previously had a baby who was stillborn, or born with a birth defect
- have an unusually large amount of amniotic fluid (the cushioning fluid within the uterus that surrounds the developing fetus)
- are over 30 years of age
- belong to an ethnic group known to experience higher rates of gestational diabetes
- have a history of gestational diabetes during a pregnancy

Causes and symptoms

Since increasing levels of pregnancy hormones cause gestational diabetes, it develops in late in pregnancy when pregnancy hormones are at their highest levels. Often women with gestational diabetes have few symptoms. However, leaving gestational diabetes undiagnosed and untreated is risky to the developing fetus. Left untreated, the mother's blood glucose levels will remain consistently high, and these same high levels will occur in the blood of the fetus. The fetal pancreas responds to the high level glucose by secreting large amounts of insulin. This insulin allows the fetal cells to take in excess glucose that is converted into fat and stored. This conversion process uses oxygen that may be needed for other fetal processes. Low oxygen levels can lead to an increased risk of heart, breathing, and vision problems. Increased fat storage causes many babies born to women with gestational diabetes to be unusually large, often large enough to cause more difficult deliveries that may require the use of forceps, suction, or **cesarean section**.

Furthermore, when the baby is born, it will have an abnormally high level of insulin in the blood. After birth, when the mother and baby are no longer attached to each other via the placenta and umbilical cord, the baby will no longer be receiving the mother's high level of blood glucose. The infant's high level of insulin, however, will quickly use up the glucose circulating in the infant's bloodstream. The baby is then at risk for having a dangerously low level of blood glucose, a condition called **hypoglycemia**. When this occurs, it is easily resolved by giving the baby glucose from an external source.

Diagnosis

Since gestational diabetes often exists with no symptoms detectable by the mother, and since its existence puts the developing baby at risk for developmental abnormalities, screening for the disorder is a routine part of pregnancy care. This screening usually is done between the 26th and 28th week of

WWW.BOOKBAZ.IR

KEY TERMS

Glucose—A simple sugar that is the final product of the breakdown of carbohydrates.

Glycemic index—A ranking from 1–100 of how much carbohydrate-containing foods raise blood sugar levels within two hours after being eaten. Foods with a glycemic index of 50 or lower are considered "good."

Hormone—A chemical messenger that is produced by one type of cell and travels through the bloodstream to change the metabolism of a different type of cell.

Insulin—A hormone produced by the pancreas that is central to the processing of sugars and carbohydrates in the diet.

Placenta—An organ that is attached to the inside wall of the mother's uterus and to the fetus via the umbilical cord. The placenta allows oxygen and nutrients from the mother's bloodstream to pass into the unborn baby.

Type 1 diabetes—A chronic immune system disorder in which the pancreas does not produce sufficient amounts of insulin, a hormone that enables cells to use glucose for energy. Also called juvenile diabetes, it must be treated with insulin injections.

Type 2 diabetes—Formerly called adult-onset diabetes. In this form of diabetes, the pancreas either does not make enough insulin or cells become insulin resistant and do not use insulin efficiently.

pregnancy. At this point in the pregnancy, the placental hormones have reached a sufficient level to cause insulin resistance. Screening for gestational diabetes involves the pregnant woman drinking a special solution that contains exactly 50 grams of glucose. An hour later, the woman's blood is drawn and tested for its glucose level. A level less than 140 mg/dL is considered normal.

When the screening glucose level is over 140 mg/dL, a special three-hour glucose tolerance test is performed. This involves following a special diet for three days before the test. This diet is set up to contain at least 150 grams of carbohydrates each day. Just before the test, the woman is instructed to eat and drink nothing except water for 10–14 hours. A blood sample is then tested to determine the **fasting** glucose level. The woman then drinks a special solution containing exactly 100 grams of glucose, and her blood is tested every hour for the next three hours. If two or more of these levels are elevated over normal, then the woman is considered to have gestational diabetes.

Treatment

Treatment for gestational diabetes depends on the severity of the diabetes. Mild forms can be treated with changes in diet. Women may be put on strict, detailed **diets**, and instructed to stay within a certain range of calorie intake. Exercise sometimes is used to help reduce blood glucose levels. Women often are asked to regularly measure their blood glucose level. This is done by poking a finger with a needle called a lancet, putting a drop of blood on a special type of paper, and feeding the paper into a meter that analyzes and reports the blood glucose level. Self-monitoring of blood glucose helps to manage gestational diabetes and prevent complications. When diet and exercise do not keep blood glucose levels within an acceptable range, a woman may need to take regular shots of insulin.

Prognosis

Prognosis for women with gestational diabetes and their infants is generally good. Almost all such women have blood glucose levels that return to normal after the birth of their baby. However, research has shown that nearly half of these women who have gestational diabetes will develop type 2 diabetes within 15 years.

Pregnant women who have type 1 or type 2 diabetes that is poorly controlled have 4–8 times the chance of having a baby born with a birth defect than women who do not have diabetes. The risk is much lower for babies born to women who develop gestational diabetes because their fetus is exposed to high glucose levels for a much shorter time and only near the end of pregnancy after most organs are already formed. However, the child of a mother with gestational diabetes has a greater-than-normal chance of developing diabetes sometime in adulthood. A woman who has had gestational diabetes during one pregnancy has about a 68% chance of having it again during any subsequent pregnancies. Women who had gestational diabetes usually have their blood glucose levels tested at the post-partum checkup or after stopping **breastfeeding**.

Prevention

There is no known way to prevent gestational diabetes since it is caused by the effects of normal hormones of pregnancy. However, the effects of insulin resistance can be best handled through careful attention to diet, avoiding becoming overweight throughout life, and participating in reasonable exercise and avoiding **smoking**.

GI bleeding studies

Definition

GI bleeding studies uses radioactive materials in the investigation of bleeding from the gastrointestinal (GI) tract. These studies go under various names such as "GI bleeding scans" or "tagged red blood cell scans." They are performed and interpreted by radiologists (physicians who specialize in diagnosis and

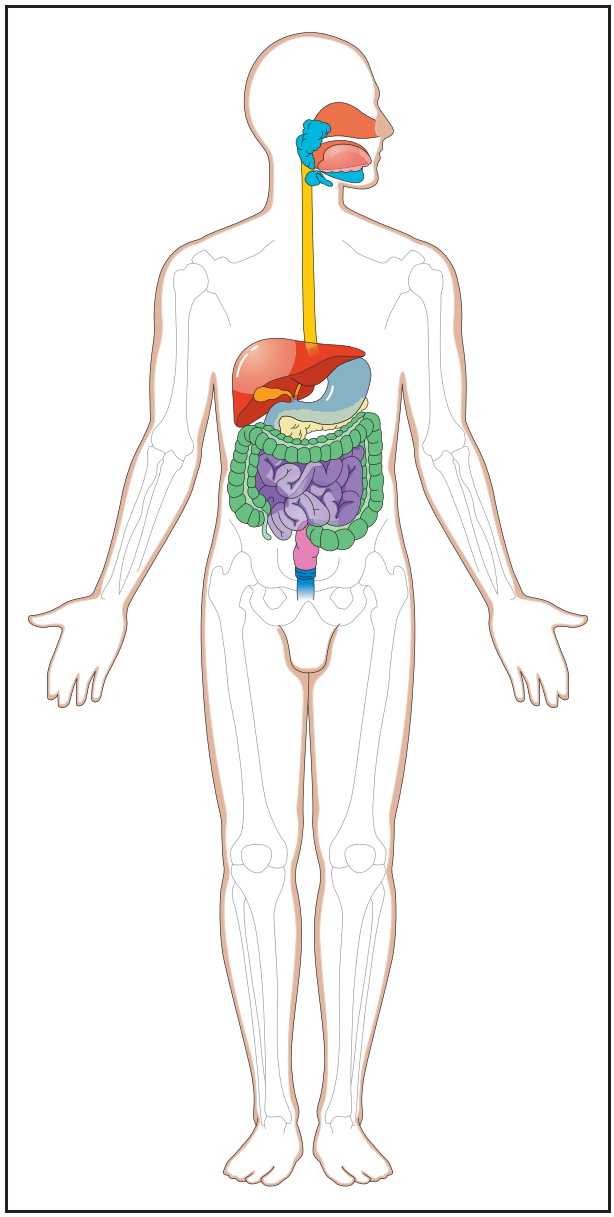

Diagram of the human digestive system. *(Illustration by Argosy, Inc. © Cengage Learning®.)*

WWW.BOOKBAZ.IR

treatment of diseases by means of x rays or related substances).

Purpose

These studies are designed to find the source of blood loss from the GI tract; that is the stomach, small bowel, or colon. They work best when bleeding is either too slow, intermittent, or too rapid to be identified by other means, such as **endoscopy**, upper GI series, or **barium enema**.

They are particularly useful when other methods have not been able to determine the site or cause of bleeding.

Precautions

Because of the use of radioactive materials, these studies are best avoided in pregnant patients. Another important relates to the interpretation of these tests, whether normal or abnormal. Since these studies are far from perfect, they can only be used as "guides" as to the cause or site of bleeding. In most instances, further studies must be performed to confirm their findings.

Description

Bleeding scans are based on the accumulation of radioactive material as it exits from the vessels during a bleeding episode. Blood is first withdrawn from the patient. Then, the blood, along with a radioactive substance is injected into a vein and over several hours scans measuring radioactivity are performed. The studies were initially reported to be very sensitive and accurate; however, critical evaluation of these tests have shown them to be less accurate than originally believed.

Preparation

No preparation is needed for these tests. They are often done on an "emergency" basis.

Aftercare

No special care is needed after the exam.

Results

A normal exam would fail to show any evidence of accumulation of radioactive material on the scan. However, scans may be normal in as many as 70% of patients who later turn out to have significant causes of bleeding. This is known as a false-negative result. A patient must be bleeding at the same time the scan is performed for it to be seen. Therefore, not finding evidence of a bleeding source during the study, can be misleading.

KEY TERMS

Endoscope, Endoscopy—An endoscope as used in the field of gastroenterology is a thin flexible tube which uses a lens or miniature camera to view various areas of the gastrointestinal tract. The performance of an exam using an endoscope is referred by the general term endoscopy. Diagnosis through biopsies or other means and therapeutic procedures can be done with these instruments.

Abnormal

The accumulation of radioactive material indicating a "leakage" of blood from the vessels is abnormal. The scan gives a rough, though not exact, guide as to the location of the bleeding. It can tell where the bleeding may be, but usually not the cause. Thus, extreme caution and skill is needed in interpreting these scans, and decisions involving surgery or other treatment should await more definitive tests.

Risks

Bleeding scans are free of any risks or side-effects, aside from the fact that they should best be avoided in **pregnancy**.

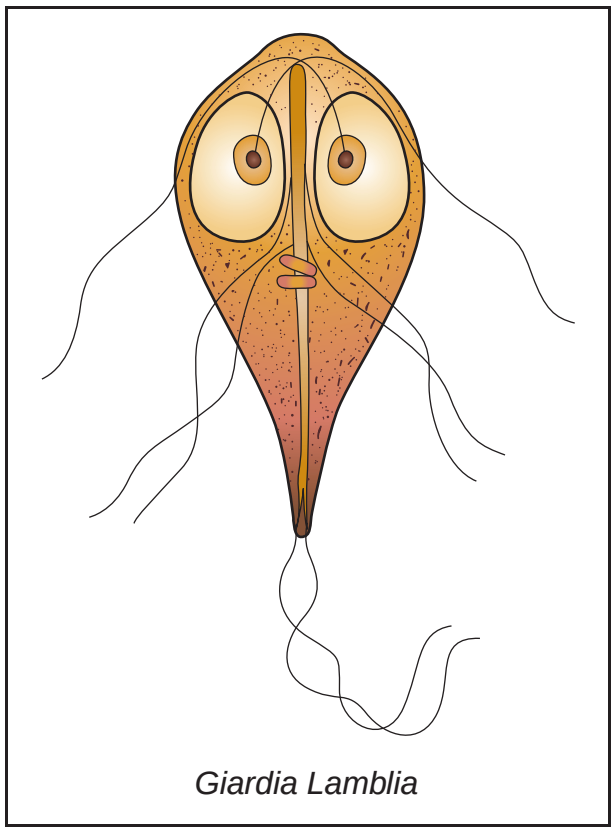
Giardia lamblia infection *see* **Giardiasis**

Giardiasis

Definition

Giardiasis is a common intestinal infection spread by eating contaminated food, drinking contaminated water, or through direct contact with the organism that causes the disease, *Giardia lamblia*. Giardiasis is found throughout the world and is a common cause of traveller's **diarrhea**. In the United States it is a growing problem, especially among children in childcare centers.



Infection with the protozoon *Giardia lamblia*, shown above, causes diarrhea in humans. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Description

Giardia is one of the most common intestinal parasites in the world, infecting as much as 20% of the entire population of the earth. It is common in overcrowded developing countries with poor sanitation and a lack of clean water. Recent tests have found *Giardia* in 7% of all stool samples tested nationwide, indicating that this disease is much more widespread than was originally believed. It has been found not only in humans, but also in wild and domestic animals.

Giardiasis is becoming a growing problem in the United States, where it affects three times more children than adults. In recent years, giardiasis outbreaks have been common among people in schools or daycare centers and at catered affairs and large public picnic areas. Children can easily pass on the infection by touching contaminated toys, changing tables, utensils, or their own feces, and then touching other people. For this reason, infection spreads quickly through a daycare center or institution for the developmentally disabled.

Unfiltered streams or lakes that may be contaminated by human or animal wastes are a common source of infection. Outbreaks can occur among campers and hikers who drink untreated water from mountain streams. While 20 million Americans drink unfiltered city water from streams or rivers, giardiasis outbreaks from tainted city water have been rare. Most of these problems have occurred not due to the absence of filters, but because of malfunctions in city water treatment plants, such as a temporary drop in chlorine levels. It is possible to become infected in a public swimming pool, however, since *Giardia* can survive in chlorinated water for about 15 minutes. During that time, it is possible for an individual to swallow contaminated pool water and become infected.

Causes and symptoms

Giardiasis is spread by food or water contaminated by the *Giardia lamblia* protozoan organism found in the human intestinal tract and feces. When the cysts are ingested, the stomach acid degrades the cysts and releases the active parasite into the body. Once within the body, the parasites cling to the lining of the small intestine, reproduce, and are swept into the fecal stream. As the liquid content of the bowel dries up, the parasites form cysts, which are then passed in the feces. Once excreted, the cysts can survive in water for more than three months. The parasite is spread further by direct fecal-oral contamination, such as can occur if food is prepared without adequate hand-washing, or by ingesting the cysts in water or food.

Giardiasis is not fatal, and about two-thirds of infected people exhibit no symptoms. Symptoms will not occur until between one and two weeks after infection. When present, symptoms include explosive, watery diarrhea that can last for a week or more and, in chronic cases, may persist for months. Because the infection interferes with the body's ability to absorb fats from the intestinal tract, the stool is filled with fat. Other symptoms include foul-smelling and greasy feces, stomach pains, gas and bloating, loss of appetite, **nausea and vomiting**. In cases in which the infection becomeschronic, lasting for months or years, symptoms might include poor digestion, problems digesting milk, intermittent diarrhea, **fatigue**, weakness, and significant weight loss.

Diagnosis

Diagnosis can be difficult because it can be easy to overlook the presence of the giardia cysts during a

KEY TERMS

Antibody—A specific protein produced by the immune system in response to a specific foreign protein or particle called an antigen.

Antigen—A substance (usually a protein) identified as foreign by the body's immune system, triggering the release of antibodies as part of the body's defense mechanism.

Enzyme-linked immunosorbent assay (ELISA)—A laboratory technique used to detect specific antigens or antibodies. It can be used to diagnose giardiasis.

Giardia lamblia—A type of protozoa with a whip-like tail that infects the human intestinal tract, causing giardiasis. The protozoa will not spread to other parts of the body.

Immunocompromised—A state in which the immune system is suppressed or not functioning properly.

routine inspection of a stool specimen. In the past, the condition has been diagnosed by examining three stool samples for the presence of the parasites. However, because the organism is shed in some stool samples and not others, the infection may not be discovered using this method.

A newer, more accurate method of diagnosing the condition is the enzyme-linked immunosorbent assay (ELISA) that detects cysts and antigen in stool, and is approximately 90% accurate. While slightly more expensive, it only needs to be done once and is therefore less expensive overall than the earlier test.

Treatment

Acute giardiasis can usually be allowed to run its natural course and tends to clear up on its own. **Antibiotics** are helpful, however, in easing symptoms and preventing the spread of infection. Medications include metronidazole, furazolidone and paromomycin. Healthy carriers with no symptoms do not need antibiotic treatment. If treatment should fail, the patient should wait two weeks and repeat the drug course. Anyone with an impaired immune system (immunocompromised), such as a person with **AIDS**, may need to be treated with a combination of medications.

Prognosis

Giardiasis is rarely fatal, and when treated promptly, antibiotics usually cure the infection. While most people respond quickly to treatment, some have lingering symptoms and suffer with diarrhea and cramps for long periods, losing weight and not growing well. Those most at-risk for a course like this are the elderly, people with a weakened immune system, malnourished children, and anyone with low stomach acid.

Prevention

The best way to avoid giardiasis is to avoid drinking untreated surface water, especially from mountain streams. The condition also can be minimized by practicing the following preventive measures:

- thoroughly washing hands before handling food
- maintaining good personal cleanliness
- boiling any untreated water for at least three minutes
- properly disposing of fecal material

Children with severe diarrhea (and others who are unable to control their bowel habits) should be kept at home until the stool returns to normal. If an outbreak occurs in a daycare center, the director should notify the local health department. Some local health departments require a follow-up stool testing to confirm that the person is no longer contagious. People not in high-risk settings can return to their routine activities after recovery.

Ginkgo biloba

Definition

Ginkgo biloba is an herbal dietary supplement made from the leaves of the tree *Ginkgo biloba*.

Purpose

Ginkgo biloba, sometimes called *bai guo*, has been used in **Traditional Chinese Medicine** (TCM) for about 5,000 years to treat **memory loss**, mood, nerve, circulatory and many other health problems. Ginkgo biloba often is combined with **ginseng** to boost memory, improve the quality of life, and increase a sense of well-being. The effectiveness of some TCM uses of ginkgo, such as relieving **pain** caused by clogged arteries in the leg (claudication), treating Alzheimer's disease, and improving blood flow to the brain have been evaluated in well-designed studies and are generally accepted by practitioners of conventional medicine. Many other TCM uses of ginkgo biloba are currently being investigated.

Ginkgo biloba leaves. *(© iStockPhoto/Ma Sai.)*

Description

Ginkgo biloba is the last existing member of an ancient family of trees. The fossil record shows that ginkgo trees existed 200 million years ago. *Ginkgo biloba* is native to China, Japan, and Korea. The tree was introduced to North America in the 1700s. Ginkgo trees grow to a height of 65–115 ft (20–35 m). They are extremely resistant to disease and insect damage and can live for several hundred years. Female trees produce bad-smelling fruit-like bodies the size of an apricot that contains seeds. Herbal practitioners sometimes use the seeds in treatment. The much cleaner male ginkgo is a popular tree for urban landscaping.

The fan-shaped leaves of the ginkgo are used for medicinal purposes. About 20 different compounds have been identified in ginkgo leaves, but the medically active ingredients appear to be flavonoids and terpenoids. Flavonoids are **antioxidants** that help lower the level of free radicals in the body. Terpenoids are thought to protect nerves from damage, reduce inflammation, and decrease blood clotting.

In the United States, *Ginkgo biloba* is cultivated and the leaves are harvested and dried, then often used to make a standardized extract that contains 24–25% flavonoids and 6% terpenoids. United States law does not require the standardization of dietary supplements, so consumers should read all labels carefully. Ginkgo biloba is often sold as capsules and tablets. Dry and liquid ginkgo extract is added to other herbal remedies as well as teas, energy or health bars, and similar products. An injectable form of ginkgo biloba extract that was available in Europe has been withdrawn from the market because of adverse side effects. Most well-designed studies have been done using a total of 80–240 mg of 50:1 standardized extract divided into 2 or 3 doses daily and taken by mouth.

Regulation of ginkgo biloba sales

Ginkgo biloba is one of the top selling herbal remedies in the United States and is even more popular in Europe. Under the 1994 Dietary Supplement Health

WWW.BOOKBAZ.IR

and Education Act (DSHEA), the sale of ginkgo biloba is regulated by the U.S. Food and Drug Administration (FDA) as a dietary supplement. At the time the act was passed, legislators felt because many dietary supplements such as ginkgo biloba come from natural sources and have been used for hundreds of years by practitioners of complementary and alternative medicine (CAM), supplements did not need to be regulated as rigorously as prescription and over-the-counter drugs used in conventional medicine.

The DSHEA regulates ginkgo biloba in the same way that food is regulated. Like food manufacturers, manufacturers of herbal products containing ginkgo biloba do not have to prove that they are either safe or effective before they can be sold to the public. This differs from conventional pharmaceutical drugs, which must undergo extensive human testing to prove their safety and effectiveness before they can be marketed. Also unlike conventional drugs, the label for a dietary supplement such as ginkgo biloba does not have to contain any statements about possible side effects. All herbal supplements sold in the United States must show the scientific name of the herb on the label.

Health claims

Ginkgo biloba is one of the most promising traditional herbs investigated by Western medicine. The National Center for Complementary and Alternative Medicine (NCCAM), a government organization within the National Institutes of Health, is sponsoring clinical trials to determine safety and effectiveness of ginkgo biloba as a treatment for more than a dozen diseases and disorders.

Some health claims for ginkgo biloba have already been evaluated in large, well-controlled studies that satisfy the proof of safety and effectiveness demanded by conventional medicine. There is good evidence that ginkgo biloba can cause short-term improvement in mental function in people with Alzheimer's disease. In a well-designed study, ginkgo biloba was as effective as the prescription drug donepezil (Aricept) in slowing the development of **dementia** in people with mild to moderate Alzheimer's. Ginkgo biloba has also been shown to be effective in improving blood flow to the brain and in treating certain other dementias. The effect of ginkgo biloba on memory in healthy young adults and in people with age-related memory impairment is inconsistent, but strong enough to continue to study the effects of the herb in these populations.

In other rigorous studies, ginkgo biloba has improved symptoms of claudication. Claudication is leg pain that occurs during walking when insufficient oxygen reaches the leg muscles. It is usually caused by blocked arteries in the leg. Ginkgo biloba's ability to reduce blood clotting ("thin the blood") is thought to account for improving symptoms in people with claudication. However, **exercise** and prescription medication were more effective in reducing leg pain due to claudication than ginkgo biloba alone. Ginkgo biloba has also been used, especially in Europe, to treat Raynaud's disease. Raynaud's disease causes the extremities of the body to feel cold in response to **stress** or cool temperatures. During an attack of Raynaud's disease, the blood vessels to the affected area narrow and blood flow is reduced.

Several health claims for ginkgo biloba center on treating disorders of the eye, including **glaucoma**, age-related **macular degeneration**, and type 2 diabetes-related retinopathy. Ginkgo appears to increase blood flow to the eye, but additional studies need to be done to evaluate its effectiveness in helping to treat these disorders.

The terpenoids in ginkgo biloba are thought to help prevent nerve damage. Because of this, ginkgo has been suggested as a treatment for **tinnitus** (ringing of the ears), **multiple sclerosis**, cochlear deafness, and Huntington's disease. Results of studies so far are inconsistent, and additional research is needed to determine the usefulness of ginkgo in nerve disorders.

Some researchers have suggested that ginkgo biloba is useful in treating depression, **seasonal affective disorder**, **premenstrual syndrome**, **altitude sickness**, vertigo (**dizziness**), premenstrual syndrome (PMS), gastric cancer, side effects of anti-cancer drugs, and pulmonary interstitial fibrosis, as well as generally improving quality of live and sense of well-being. Further studies need to be done to evaluate these health claims.

Precautions

Ginkgo biloba seeds contain toxins that can cause **vomiting**, seizures, loss of consciousness, and death, especially in young children. Ginkgo biloba seeds are not safe and should be avoided.

Extracts of the leaf of *Ginkgo biloba* are generally safe and cause few side effects when taken at recommended doses for up to six months. People who are planning to have surgery should stop taking ginkgo biloba at least two days before their operation because of the risk of increased bleeding. The safety of ginkgo biloba in children and pregnant and **breastfeeding** women is still being studied.

Interactions

Ginkgo biloba has blood-thinning properties and is likely to increase the blood-thinning and anticoagulant effects of medicines such as warfarin (Coumadin), clopidogrel (Plavix), **aspirin**, and **nonsteroidal anti-inflammatory drugs** (e.g., Advil, Motrin). Individuals taking these drugs should not begin taking ginkgo biloba without consulting their healthcare provider.

Ginkgo biloba may also interact with monoamine-oxidase inhibitors (MAOIs) used to treat certain kinds of depression and mental illness. Examples of MAOIs include isocarboxazid (Marplan), phenelzine (Nardil) and tranylcypromine (Parnate). Individuals taking MAOIs along with ginkgo biloba may experience increased effects from the MAOI.

Some reports suggest that ginkgo biloba lowers blood sugar levels. Individuals who are taking insulin or other medications that also lower blood sugar, and those with type 2 diabetes, should consult their healthcare provider before starting to take ginkgo biloba.

Risks

Serious side effects of ginkgo biloba are rare. The most common mild side effects are **headache**, dizziness, nausea, **diarrhea**, increased restlessness, and racing heart. Increased bleeding may occur. Allergic reactions to ginkgo are possible, but uncommon. In severe rare cases, the skin blisters and sloughs off, a condition called Stevens-Johnson syndrome. People who are allergic to sumac, mango rind, cashews, **poison oak**, and **poison ivy** are at slightly higher risk to have an allergic reaction to ginkgo biloba.

Parents should be aware that the safe dose of many herbal supplements has not been established for children. Accidental overdose may occur if children are give adult herbal supplements.

Ginseng

Definition

Ginseng refers to two closely related herbs of the genus *Panax*. Asian ginseng (*P. ginseng*) and American ginseng (*P. quinquefolius*) have traditionally been used for healing. Asian ginseng is also known as Korean red ginseng, Chinese ginseng, Japanese ginseng, ginseng radix, ninjin, sang, and ren shen. American ginseng is also known as Canadian ginseng, North American ginseng, Ontario ginseng, Wisconsin ginseng, red berry, sang, and ren shen. Siberian ginseng (*Eleutherococcus senticosus*) is a plant with different properties that belongs to a completely different genus. Ginseng in this entry refers only to Asian and American ginseng of the genus *Panax*.

Dried Korean ginseng. *(Custom Medical Stock Photo, Inc.)*

Purpose

Ginseng has been used for about 2,000 years in **Traditional Chinese Medicine** (TCM) to boost energy, hasten recovery from illness or injury, reduce **stress**, improve mental and physical performance (including sexual performance) and to treat several dozen different infections, gastrointestinal disorders, circulatory problems, and conditions as diverse as **burns**, cancers, diabetes, migraine headaches, and weight loss. The genus name *Panax* means "heal all," and ginseng is considered by herbalists to be an almost universal remedy. Most of these traditional uses of ginseng have not yet been substantiated by conventional medicine, however encouraging results from some well-designed, controlled human studies strongly suggest that ginseng may improve mental performance and have other health benefits.

Description

Ginseng is a perennial herb that grows in cool, damp, shady forests. Asian ginseng is native to Northern China and today is grown as a cash crop in China, Korea, Japan, and Russia. American ginseng once grew wild from the Appalachian Mountains to Minnesota. Today it is cultivated mainly in Wisconsin and in the Canadian provinces of Ontario and British Columbia. Most cultivated ginseng from North America is exported to Asia. In both Asia and North America, wild ginseng is threatened with extinction from over harvesting. In the United States, a government permit is usually required to export wild ginseng. High-quality wild ginseng is very expensive. Illegal harvesting of wild ginseng from public lands is an ongoing law enforcement problem for the United States Fish and Wildlife Service.

Ginseng is a slow-growing plant that reaches a height of 12–30 in and produces red berries. Only the root is used for medicinal purposes. Ginseng is difficult to cultivate. Plants must grow four to six years before the roots can be harvested. Ginseng roots are forked and twisted, looking somewhat like a miniature human body. They are occasionally used fresh but more often are dried and ground or powdered. The root can be soaked to make an extract or tincture. Ground ginseng can be added to tea and powered ginseng put into capsules. Ginseng extract can be added to products as diverse as chewing gum and soft drinks. Ginseng is sold under dozens of different brand names. It is often found in multi-herb remedies

sold under a huge variety of names. The active ingredients in ginseng are thought to be more than 20 compounds called ginsenosides. Some manufacturers standardize the amount of ginsenosides in their product while others do not. Standardized products usually contain 4% ginsenosides.

Regulation of ginseng sales

In the United States, ginseng is regulated by the Food and Drug Administration (FDA) as a dietary supplement under the 1994 Dietary Supplement Health and Education Act (DSHEA). At the time the act was passed, legislators felt because many dietary supplements such as ginseng come from natural sources and have been used for hundreds of years by practitioners of complementary and alternative medicine (CAM), these supplements did not need to be regulated as rigorously as prescription and over-the-counter drugs used in conventional medicine.

The DSHEA regulates ginseng in the same way that food is regulated. Like food manufacturers, manufacturers of herbal products containing ginseng do not have to prove that they are either safe or effective before they can be sold to the public. This differs from conventional pharmaceutical drugs, which must undergo extensive human testing to prove their safety and effectiveness before they can be marketed. Also unlike conventional drugs, the label for a dietary supplement such as ginseng does not have to contain any statements about possible side effects. All herbal supplements sold in the United States must show the scientific name of the herb on the label. Consumers should look for ginseng of the *Panax* variety. Sometimes less expensive herbs such as Siberian "ginseng" are substituted for true ginseng.

Health claims

Dozens of health claims are made for ginseng, many based on traditional or folk use of the herb. These claims are difficult to substantiate in ways that satisfy conventional medicine for several reasons including:

- The amount and strength of ginseng in dietary supplements is not standardized and a wide range of doses are used in different studies.
- Ginseng is often one of several herbs contained in herbal remedies, making it difficult to tell if the effects are due to ginseng or another herb.
- Many studies done on ginseng are poorly designed so that it is impossible to show a direct link between cause and effect, or they poorly reported, making analysis of the results difficult.
- Many rigorous and well-designed human studies have a small sample size.
- Many studies are sponsored by ginseng growers, manufacturers, or importers who have a financial interest in obtaining positive results.

Despite these drawbacks, there is enough evidence that ginseng provides health benefits that the National Center for Complementary and Alternative Medicine (NCCAM), a government organization within the National Institutes of Health, is sponsoring clinical trials to determine safety and effectiveness of ginseng as a treatment for several diseases and disorders.

Some health claims for ginseng appear more promising than others. There is good evidence that ginseng can cause short-term improvement in mental performance in both healthy young adults and elderly ill adults. Not enough information is available to determine if long-term gains also occur, but the results have been promising enough that ginseng is being studied in patients with Alzheimer's disease and other dementias. Along with improved mental performance, some studies have shown that ginseng improves the sense of well-being and quality of life. Results of these studies are mixed, with some finding improvements and others finding no change. The situation is complicated by the fact that different studies define and measure "well-being" and "quality of life" in different ways. In general, people with the worst quality of life report the most improvement.

Many claims are made that ginseng boosts the immune system, thus helping to prevent disease and promote a more rapid recovery from illness and injury. Some studies also claim that ginseng boosts the effect of **antibiotics** and improves the body's response to **influenza** vaccines. Some studies of patients with diseases that cause a low white cell count (white cells are a part of the immune system) show that white cell count increases with high doses of ginsenosides. Better studies are needed before the effect of ginseng on the immune system can be determined.

There is good evidence that ginseng lowers blood sugar in people with type 2 (non-insulin dependent) diabetes. The effect of ginseng on blood sugar in people with type 1 (insulin dependent) diabetes has not been studied enough to produce any definite findings.

Ginseng has been promoted as a preventative and/or cure for cancer. According the American Cancer Society, "There is no reliable scientific evidence that ginseng is effective in preventing or treating cancer in

WWW.BOOKBAZ.IR

humans." However, controversial evidence from some studies done in Asia suggests the possibility that ginseng powder or extract may prevent some cancers. More and better studies are needed to clarify these results.

Some studies have reported that ginseng improves stamina and athletic performance and decreases **fatigue**, while other studies find no effect. There are so many other lifestyle variables in most of these studies that it is difficult to separate the effect of ginseng from other factors.

Studies of the effect of ginseng on the circulatory system are mixed. Some studies find that ginseng lowers blood pressure and in combination with other herbs prevents **coronary artery disease** and possibly **congestive heart failure**. Other studies find no effect, or that the effect is apparent only at very high, and possibly unsafe, doses. The effect of ginseng on the circulatory system continues to be investigated.

Many other health claims are made for herbal mixtures that contain ginseng. These claims are extremely difficult to evaluate because of the number of variables, including the strength of the mixture, the effects of the different herbs, and potential interactions among other herbs. Until much more is known about the chemical properties and active ingredients of common medicinal herbs, it is almost impossible to evaluate these mixtures in a way that satisfies the demands of conventional medicine.

Precautions

Ginseng is generally safe and causes few side effects when taken at recommended doses. The generally recommended dose is 100–200 mg of standardized ginseng extract containing 4% ginsenosides once or twice daily. The safety of ginseng in children and pregnant and **breastfeeding** women has not been studied. Pregnant and breastfeeding women should be aware that some tinctures of ginseng contain high levels of alcohol. Some herbalists recommend that individuals take ginseng for two to three weeks and then take a break of one to two weeks before beginning the herb again.

Independent laboratory analyses have repeatedly found that many products labeled as ginseng contain little or none of the herb. True ginseng is expensive, and unscrupulous manufacturers often substitute low-cost herbs for ginseng. Another problem is that some ginseng products have been found to be contaminated with pesticides and other chemicals that can cause serious side effects.

Interactions

Ginseng appears to interact with blood-thinning and anti-coagulant medicines such as warfarin (Coumadin), clopidogrel (Plavix), **aspirin**, and **nonsteroidal anti-inflammatory drugs** (e.g., Advil, Motrin). Individuals taking these drugs should not begin taking ginseng without consulting their healthcare provider.

Because ginseng lowers blood sugar levels, individuals who are taking insulin or other medications that also lower blood sugar, and those with type 2 diabetes, should be monitored for low blood sugar if they begin taking ginseng. Adjustments are needed in their other medications.

Ginseng may also interact with monoamine-oxidase inhibitors (MAOIs) used to treat certain kinds of depression and mental illness. Examples of MAOIs include isocarboxazid (Marplan), phenelzine (Nardil) and tranylcypromine (Parnate). Individuals taking MAOIs with ginseng may develop **headache**, **tremors**, increased **anxiety**, restlessness, sleeplessness, and **mania**.

Preliminary evidence suggests that ginseng may interact with certain blood pressure and heart medications. The herb may also interfere with the way the liver processes other drugs and herbs. Before beginning to take a supplement containing ginseng, individuals should review their current medications with their healthcare provider to determine any possible interactions.

Risks

Serious side effects of ginseng are rare. The most common side effects are increased restlessness, **insomnia**, nausea, **diarrhea**, and rash. Allergic reactions are possible, but uncommon. Some of the more serious side effects reported are thought to be the result of contamination with pesticides, heavy metals, or other chemicals rather than a side effect caused by ginseng.

Parents should be aware that the safe dose of many herbal supplements has not been established for children. Accidental overdose may occur if children are give adult herbal supplements.

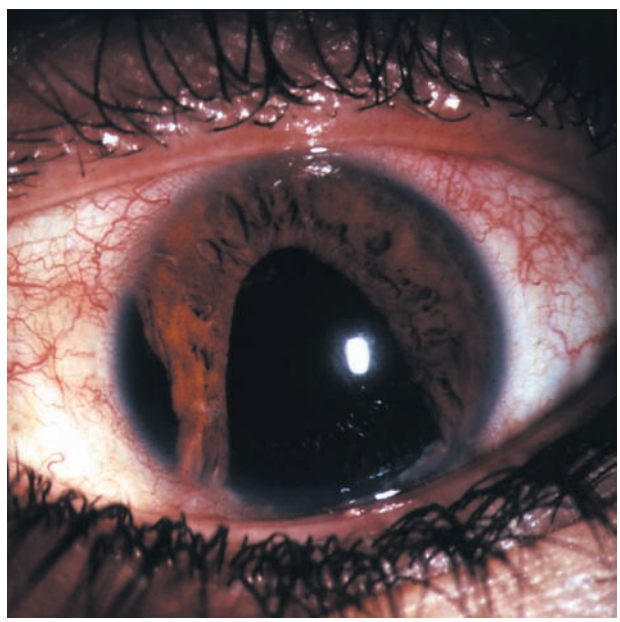
Tish Davidson, AM

Glaucoma

Definition

Glaucoma is a condition in which the optic nerve is subject to damage—usually, but not always, because of excessively high intraocular pressure (pressure within the eye, also called IOP). If untreated, the optic nerve damage results in progressive, permanent vision loss, starting with unnoticeable blind spots in the field of vision, progressing to tunnel vision, and then to blindness. Glaucoma can result in irreversible damage to the optic nerve. It is one of the leading



A close-up view of an inflamed eye with acute glaucoma and an irregularly enlarged pupil. *(Custom Medical Stock Photo, Inc.)*

WWW.BOOKBAZ.IR

causes of irreversible blindness in the United States and world-wide, and is the leading cause of blindness among African Americans and older adults in the United States. Because there are usually no symptoms early on in the disease, about half of the people with glaucoma do not even know they have the condition.

Description

More than two million people in the United States have glaucoma, and 80,000 of those are legally blind as a result of the disease. Glaucoma can strike any age group, even newborn infants. Susceptibility to the disease, however, increases with age. African Americans are at a three times higher risk of glaucoma than the rest of the population.

Glaucoma is a class of diseases. There are at least 20 different forms that can be divided into two categories: open-angle glaucoma and narrow-angle glaucoma. To understand what glaucoma is and what these terms mean, it is useful to understand eye structure.

Eyes are sphere-shaped. A tough, non-leaky protective sheath (the sclera) covers the entire eye, except for the clear cornea at the front and the optic nerve at the back. Light comes into the eye through the cornea, then passes through the lens, which focuses it onto the retina (the innermost surface at the back of the eye). The rods and cones of the retina transform the light energy into electrical messages, which are transmitted to the brain by the bundle of nerves known as the optic nerve.

The iris, the colored part of the eye shaped like a round picture frame, is between the dome-shaped cornea and the lens. It controls the amount of light that enters the eye by opening and closing its central hole (pupil) like the diaphragm in a camera. The iris, cornea, and lens are bathed in a liquid called the aqueous humor, which is somewhat similar to plasma. This liquid is continually produced by nearby ciliary tissues and moved out of the eye into the bloodstream by a system of drainage canals (called the trabecular meshwork). The drainage area is located in front of the iris, in the angle formed between the iris and the point at which the iris appears to meet the inside of the cornea.

Glaucoma occurs if the aqueous humor is not removed rapidly enough or if it is made too rapidly, causing pressure to build-up. The high pressure distorts the shape of the optic nerve and destroys the nerve. Destroyed nerve cells result in blind spots in places where the image from the retina is not being transmitted to the brain.

Open-angle glaucoma accounts for over 90% of all cases. It is called "open-angle" because the angle between the iris and the cornea is open, allowing drainage of the aqueous humor. It is usually chronic and progresses slowly. In narrow-angle glaucoma, the angle where aqueous fluid drainage occurs is narrow, and therefore may drain slowly or may be at risk of becoming closed. A closed-angle glaucoma attack is usually acute, occurring when the drainage area is blocked. This can occur, for example, if the iris and lens suddenly adhere to each other and the iris is pushed forward. In patients with very narrow angles, this can occur when the eyes dilate (e.g., when entering a dark room, or if taking certain medications).

Congenital glaucoma occurs in babies and is the result of incomplete development of the eye's drainage canals during embryonic development. An infant with congenital glaucoma may have enlarged, hazy corneas; show signs of being extremely sensitive to light; and have very teary eyes. The eye may also seem enlarged or bulging. The best way to detect childhood glaucoma is for children to have a regular and complete **eye examination**. **Microsurgery** can often correct the defects or they can be treated with a combination of medicine and surgery.

One rare form of open-angle glaucoma, normal tension glaucoma, is different. People with normal-tension glaucoma have optic nerve damage in the presence of normal IOP. The mechanism of this disease is a mystery but is generally detected after an examination of the optic nerve. Those at higher risk for this form of glaucoma are people with a familial history of normal tension glaucoma, people of Japanese ancestry, and people with a history of systemic **heart disease** such as irregular heart rhythm.

Glaucoma is also a secondary condition of over 60 widely diverse diseases and can also result from injury, inflammation, tumor, or in advanced cases of cataract or diabetes.

Nursing and allied health professionals play an important part in the diagnosis and treatment of glaucoma. Skilled ophthalmic technicians and assistants record the patient history and perform many of the preliminary tests. Depending on skill level, these ophthalmic assistants may perform measurement of visual acuity under both low and high illumination, assessment of ocular motility and binocularity, visual fields, measurement of IOPs with tonometers, evaluation of pupillary responses, and refraction.

Before surgical procedures, nurses and assistants also prepare the operating room (OR). Many ophthalmologists now have their own ambulatory surgery centers where skilled technicians and ophthalmic nurses play a critical role in preparing the OR and patients for the surgery. Ophthalmic nurses also assist the ophthalmologists during surgery and discuss outcomes with patients post-operatively.

Nurses and assistants assist patients by explaining the sometimes difficult regimen of glaucoma medication. In some cases, patients require several doses of a combination of medications. Ophthalmic nurses and assistants show patients the correct technique for inserting eyedrops, and reinforce the physician's instructions for medication compliance.

Patient education

Ophthalmic assistants and nurses help to ensure that patients return to the physician's office in a timely manner so that IOPs can be monitored. Nurses and assistants also emphasize the importance of adhering to the eyedrop schedule to keep IOPs at a lower level, and answer any questions concerning proper eyedrop instillation.

Causes and symptoms

Causes

Glaucoma is the result of disruptions of normal processes to maintain pressure within the eye tissue. The iris, cornea, and lens of the eye are bathed in a nutritive liquid called the aqueous humor, which is made by cells within the eye. Excess fluid is continually removed by a spongy meshwork of drainage canals. Glaucoma occurs if there is a build up of the aqueous humor due to poor drainage or overproduction. As the fluid builds up there is increased pressure on the retina at the back of the eye. This increased pressure reduces the blood supply to the nerves of the retina and causes the nerves to die, which may distort and destroy the optic nerve. As nerve cells are destroyed, blind spots develop, and there is a progressive loss of vision. A change in the production and strength of collagen may also contribute to the onset of the disease. Collagen is a protein that helps maintain the structure and function of eye tissue. **Stress** and **allergies** may aggravate glaucoma symptoms.

It is probable that most cases of glaucoma are partially due to a genetic predisposition. At least 10 defective genes have been identified that may cause glaucoma. Although in the late 2000s there were still many unknown factors that trigger the disease, a number of processes have been implicated. They include age-related changes, congenital abnormalities, injuries to the eye tissue, and problems related to other eye diseases. Vision loss in all forms of glaucoma is caused by damage to the optic nerve, the retina, and the collagen protein that makes up eye tissue. Use of certain medications, including antihypertensives, **antihistamines**, anticholinergics, and antidepressants may also contribute to the development of glaucoma. Corticosteroid eye drops, which are often used for other eye disorders, may destroy the integrity of eye tissue. Other types of eye drops may cause the pupils to dilate, increasing intraocular eye pressure (IOP), which may also lead to glaucoma in those who have a tendency to the disease.

Symptoms

Chronic open-angle glaucoma at first develops without noticeable symptoms. The pressure buildup is gradual, and it does not bring on discomfort. Moreover, the vision loss is too gradual to be noticed at first, and the brain compensates for blind spots. Over an extended period of time, though, the elevated pressure pushes against and damages the optic nerve and the retina. If glaucoma is left untreated, vision loss becomes evident, and the condition becomes painful.

Acute closed-angle glaucoma is obvious from the beginning. The symptoms are blurred vision, severe eye **pain**, sensitivity to light, **nausea and vomiting**, dilated pupils, reddened eyes, and halos visualized around lights. The corneas may become hazy in appearance. Acute closed-angle glaucoma is an emergency situation. It needs to be treated immediately. Congenital glaucoma is evident at birth. Symptoms are bulging eyes, cloudy corneas, enlarged corneas, excessive teariness, and sensitivity to light.

Risk factors that increase the probability of developing glaucoma include:

- ocular hypertension, a slightly increased IOP
- age over 40
- diabetic conditions
- high blood pressure
- migraine headaches
- nearsightedness, farsightedness, and other visual disturbances
- a family history of glaucoma
- being of African American or Hispanic ethnicity

WWW.BOOKBAZ.IR

Diagnosis

Sometimes glaucoma can be diagnosed with a routine eye exam by an ophthalmologist, who can make a definitive diagnosis of glaucoma. IOP, defects in the field of vision, and the appearance of the optic nerve, are all considered in the diagnosis of glaucoma. Visual field tests (perimetry) can detect blind spots in a patient's field of vision before the patient is aware of them. An instrument, known as a tonometer, is used to measure eye pressure. Since IOP can vary throughout the day, a person may have to return for several visits to measure eye pressure at different times of the day. An ophthalmoscope is used to examine the inner aspects and the back of the eyes, including the optic nerve, for changes and damage. A slit lamp may be used to allow the doctor further examination of the eye. Another test, gonioscopy, can distinguish between narrow-angle and open-angle glaucoma. A gonioscope allows visualization of the angle between the iris and the cornea. A subsequent technology is optical coherence tomography (OCT) that produces high-resolution images of the anterior segment of the eye and is a non-invasive procedure. As of 2014, it was primarily used in conjunction with gonioscopy in diagnosing and assessing glaucoma.

Intraocular pressure can vary throughout the day. For that reason, the doctor may have a patient return for several visits to measure the IOP at different times of the day.

Treatment

The first line of glaucoma treatment is the use of prescription eyedrops. Several classes of medications are effective at lowering IOP and thus preventing optic nerve damage in chronic and neonatal glaucoma. **Beta blockers** (e.g., timolol), carbonic anhydrase inhibitors (e.g., acetazolamide), and alpha-2 agonists (e.g., brimonidine tartrate) inhibit aqueous humor production. Miotics (e.g., pilocarpine) and prostaglandin analogues (e.g., latanoprost) increase the outflow of aqueous humor.

It is important for patients to inform their doctors of any health conditions they have or any medications they take, including over-the counter drugs. Certain drugs used to treat glaucoma are not prescribed for patients with pre-existing conditions. The drugs prescribed to treat glaucoma all have side effects, so patients taking them should be monitored closely, especially for cardiovascular, pulmonary, and behavioral symptoms. Each medication lowers IOP by a different amount, and a combination of medications may be necessary. To ensure that IOP is lowered sufficiently, it is important that patients take their medications and be monitored regularly. IOP should be measured three to four times per year.

Normal-tension glaucoma is treated by reducing IOP to less-than-normal levels, on the theory that overly susceptible optic nerves are less likely to be damaged at lower pressures. Research underway may point to better treatments for this form of glaucoma.

Attacks of acute closed-angle glaucoma are medical emergencies. IOP is rapidly lowered by successive deployment of acetazolamide, hyperosmotic agents, a topical beta-blocker, and pilocarpine. Epinephrine should not be used because it exacerbates angle closure.

Trabeculectomy, to open the drainage canals or make an opening in the iris, can be effective in increasing the outflow of aqueous humor. This surgery is usually successful, but the effects often last less than one year. Nevertheless, this is an effective treatment for patients whose IOP is not sufficiently lowered by drugs and for those who can't tolerate the drugs.

Laser peripheral iridotomy is a procedure used almost exclusively to treat narrow angle glaucoma. It involves creating a small opening in the peripherial iris that allows aqueous fluid to drain from behind the iris directly to the anterior chamber. This procedure typically result in "opening up" the narrow angle between the iris and the cornea, in essence converting a narrow angle into an open angle.

Argon laser trabeculoplasty is usually recommended when medications have not been able to sufficiently control IOP, although it is increasingly advocated as primary therapy for patients who are not good candidates for the use of glaucoma medications or who cannot use eyedrops. In this procedure, the beam of an argon laser is directed at the trabecular meshwork. Typically about 180° of the trabecular meshwork is treated with laser spots. As a result of this procedure, the drainage of aqueous fluid out of the eye increases, thus lowering IOP.

Gene therapy may also be part of future treatments. A mutation in the gene myocilin is believed to cause most cases of juvenile glaucoma, and 3–4% of adult glaucoma. Researchers are investigating drugs that inhibit myocilin production. The drug therapy would not just treat IOP, but also could be used before glaucoma's onset.

Vitamin C, vitamin B_1 (thiamine), chromium, zinc, and rutin may reduce IOP.

Patients using alternative methods to attempt to prevent optic nerve damage should be advised they also need the care of a traditionally trained ophthalmologist or optometrist who is licensed to treat glaucoma, so that IOP and optic nerve damage can be monitored.

KEY TERMS

Agonist—A drug that mimics one of the body's own molecules.

Alpha-2 agonist—A class of drugs that bind to and stimulate alpha-2 adrenergic receptors, causing responses similar to those of adrenaline and noradrenaline, by inhibiting aqueous humor production.

Aqueous humor—A transparent liquid, contained within the eye, that is composed of water, sugars, vitamins, proteins, and other nutrients.

Beta-blocker—A class of drugs that bind beta-adrenergic receptors and thereby decrease the ability of the body's own natural epinephrine to bind to those receptors, leading to the reduction of aqueous humor secretion.

Carbonic anhydrase inhibitor—A class of diuretic drugs that inhibit the enzyme carbonic anhydrase, an enzyme involved in producing bicarbonate, which is required for aqueous humor production by the ciliary tissues in the eye. Thus, inhibitors of this enzyme inhibit aqueous humor production. Some side effects are urinary frequency, kidney stones, loss of the sense of taste, depression, and anemia.

Cornea—The clear, bowl-shaped structure at the front of the eye located in front of the colored part of the eye. The cornea lets light into the eye and partially focuses it.

Gonioscope—An instrument that consists of a magnifier and a lens equipped with mirrors and sits on the patient's cornea.

Hyperosmotic drugs—Refers to a class of drugs for glaucoma that increase the osmotic pressure in the blood, which then pulls water from the eye into the blood.

Iris—The colored part of the eye just behind the cornea and in front of the lens that controls the amount of light sent to the retina.

Laser cyclophotocoagulation—A procedure used for severe glaucoma in patients who have not responded well to previous treatments. The laser partially destroys the tissues that make the fluid of the eye.

Laser peripheral iridotomy—This procedure makes a drainage hole in the iris allowing the fluid to drain from the eye.

Laser trabeculoplasty—In this procedure the laser attempts to open the normal drainage channels of the eye so fluid can drain more effectively.

Lens (the crystalline lens)—A transparent structure in the eye that focuses light onto the retina.

Miotic—A drug that causes pupils to contract.

Ophthalmoscope—An instrument, with special lighting, designed to view structures in the eye.

Optic nerve—The nerve that carries visual messages from the retina to the brain.

Prostaglandin—A group of molecules that exert local effects on a variety of processes including fluid balance, blood flow, and gastrointestinal function.

Prostaglandin analogue—A class of drugs that are similar in structure and function to prostaglandin.

Retina—The light-sensitive layer of the eye.

Sclera—The tough, fibrous, white outer protective covering that surrounds the eye.

Tonometry—The measurement of pressure.

Trabecular meshwork—A sponge-like tissue located near the cornea and iris that functions to drain the aqueous humor from the eye into the blood.

Since the early 1970s, a number of scientific studies reported that the active agents in **marijuana** *Cannabis sativa* are effective in lowering intraocular pressure (IOP) in people with glaucoma. One study reported that people with glaucoma who smoked marijuana had a 25–30% drop in IOP that lasted three to four hours. Under federal law, the use, possession, or sale of marijuana is illegal in the United States. However, as of 2015, 23 states and District of Columbia have legalized the medical use of marijuana. In 2005, the U.S. Supreme Court ruled that federal laws against medical marijuana take precedence over state laws, allowing for continued federal prosecution against people who use marijuana for medical purposes. Despite the ruling, medical marijuana programs continue. The active agents in marijuana are cannabinol, cannabidiol, and delta-9-tetrahydrocannabinol (THC). A synthetic version of THC, dronabinol (Marinol), is available in the United States and can be legally prescribed for a number of conditions, including glaucoma.

Results

If glaucoma is left untreated, optic nerve damage will result in a progressive loss of vision. Once blindness

WWW.BOOKBAZ.IR

develops due to glaucoma, it cannot be reversed. With early treatment and monitoring, however, serious vision loss can usually be prevented.

Prevention

While glaucoma is not preventable, early detection and treatment can help to prevent serious damage to vision. Those with risk factors should have regular eye exams and avoid medicines that tend to be implicated in the development of glaucoma, including some over-the-counter cold and allergy medications. All medications should be checked for their ingredients. Alternatives for drugs that aggravate glaucoma should be discussed with a healthcare provider.

Patients with narrow angles should avoid certain medications (even over-the-counter medications, such as some cold or allergy medications).Any person who is glaucoma-susceptible (i.e. narrow angles and borderline IOPs) should read the warning labels on over-the-counter medicines and inform their physicians of products they are considering taking. **Steroids** may also raise IOP, so patients may need to be monitored more frequently if it is necessary to use steroids for another medical condition.

Gleason score

Definition

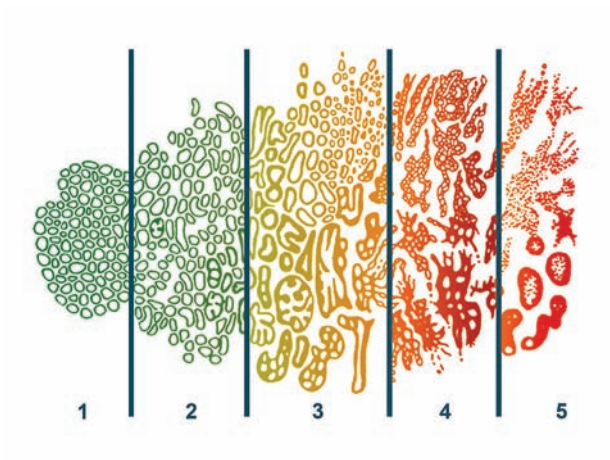
The Gleason score is a method of grading the likely speed of spread of prostate cancer on a scale from 2–10. It was developed in 1977 by Dr. Donald Gleason.

Purpose

The Gleason score, in addition to prostate specific antigen (PSA) levels and a biopsy, helps determine the likely growth of prostate cancer and helps to determine the most appropriate treatment.

Description

The prostate is a gland found only in men. It surrounds the neck of the bladder and secretes fluid that when mixed with sperm becomes semen. When



Based on the visual appearance of microscopic prostate cancer cells, a Gleason score is given. The higher the score the more advanced the prostate cancer. *(Carol & Mike Werner/ Visuals Unlimited, Inc)*

cancer of the prostate is suspected, the doctor will do a biopsy of the gland. The biopsy will tell the doctor how large the tumor is. If the cancer has spread (metastasized) to other areas of the body, additional tests will be needed.

A Gleason score is arrived at by looking at the pattern of cancerous cells in the biopsy under a microscope to see how abnormal they look. The pattern and degree of abnormality suggest how fast the cancer will grow. The pattern of cells in the biopsy is graded from 1–5, with grade 1 the most normal looking and grade 5 the most abnormal. The more abnormal the cells, the greater chance the cancer will be aggressive, growing and spreading more rapidly than cancers with less abnormal-looking cells.

- Grade 1 gland cells are small, uniform, packed closely together, and are essentially normal looking.
- Grade 2 cells look a lot like grade 1 cells, but are more loosely packed.
- Grade 3 cells are more abnormal, more loosely packed, and some gland cells have begun to move into the surrounding tissue.
- Grade 4 cells form clumps and show a breakdown in gland tissue and many cells invading the surrounding tissue.
- Grade 5 cells show a complete breakdown of the gland and most cells spreading into the tissue surrounding the gland.

The arrangement of cells in a prostate tumor usually is not uniform. To arrive at a Gleason score, the doctor examines two areas of the tumor and adds together the score of the two most common patterns seen. Thus if one area is grade 3 and the other grade 4, the Gleason score would be 3 + 4 or 7.

Tumors with Gleason scores of 2–4 are considered low risk for spreading quickly. Tumors with Gleason scores of 8–10 are considered to have a high risk of spreading quickly. Scores of 5–7 are of intermediate risk.

KEY TERMS

Biopsy—A procedure in which suspicious tissue is removed and examined by a pathologist for cancer or other disease.

Precautions

Although the Gleason score is generally predicative, it is just one factor in determining the appropriate treatment for any individual. Other factors such as the age and health of the patient will affect individual treatment plans.

Preparation

All preparation is related to performing the prostate biopsy. There is no special preparation for determining the Gleason score.

Aftercare

All aftercare is related to performing the prostate biopsy. There is no special aftercare for determining the Gleason score.

Risks

All risks are associated with the performance of the biopsy. There are no special risks associated with determining the Gleason score.

Results

The Gleason score is one factor in determining the appropriate treatment for prostate cancer in a single individual. Prostate cancers occur mainly in older men. Many prostate cancers grow slowly, and if the Gleason score is low, the most appropriate treatment may be watchful waiting. On the other hand, if the Gleason score is high, the most appropriate treatment may be surgery. The doctor will consider many factors besides the Gleason score when recommending a treatment plan.

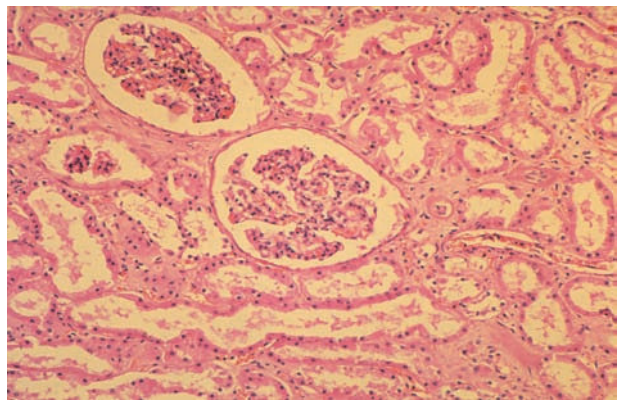
Glomerulonephritis

Definition

Acute glomerulonephritis is an inflammatory disease of both kidneys predominantly affecting children from ages two to 12. Chronic glomerulonephritis can develop over a period of 10–20 years and is most often associated with other systemic disease, including diabetes, **malaria**, hepatitis, or **systemic lupus erythematosus**.

Description

Acute glomerulonephritis is an inflammation of the glomeruli, bundles of tiny vessels inside the kidneys. The damaged glomeruli cannot effectively filter waste products and excess water from the bloodstream to make urine. The kidneys appear enlarged, fatty, and congested.



A close-up view of glomerulonephritis affecting the kidney. *(Custom Medical Stock Photo, Inc.)*

Causes and symptoms

Acute glomerulonephritis most often follows a streptococcal infection of the throat or skin. In children, it is most often associated with an upper respiratory infection, **tonsillitis**, or **scarlet fever**. Kidney symptoms usually begin two to three weeks after the initial infection. Exposure to certain paints, glue or other organic solvents may also be the causative agent. It is thought that the kidney is damaged with exposure to the toxins that are excreted into the urine.

Mild glomerulonephritis may produce no symptoms, and diagnosis is made with laboratory studies of the urine and blood. Individuals with more severe cases of the disease may exhibit:

- fatigue
- nausea and vomiting
- shortness of breath
- disturbed vision
- high blood pressure
- swelling, especially noted in the face, hands, feet, and ankles
- blood and protein in the urine, resulting in a smoky or slightly red appearance

The individual with chronic glomerulonephritis may discover their condition with a routine physical exam revealing high blood pressure, or an eye exam showing vascular or hemorrhagic changes. The kidneys may be reduced to as little as one-fifth their normal size, consisting largely of fibrous tissues.

Diagnosis

Diagnosis of glomerulonephritis is established based on medical history, combined with laboratory studies. A "dipstick" test of urine will reveal increased protein levels. A 24 hour urine collection allows measurement of the excretion of proteins and creatinine. Creatinine clearance from the bloodstream by the kidneys is considered an index of the glomerular filtration rate. Blood studies may reveal a low blood count, and may also be checked for the presence of a streptococcal antibody titer(a sophisticated blood test indicating presence of streptococcal infection). A **kidney biopsy** may also be performed, using **ultrasound** to guide the needle for obtaining the specimen.

Treatment

The main objectives in the treatment of acute glomerulonephritis are to:

- decrease the damage to the glomeruli
- decrease the metabolic demands on the kidneys
- improve kidney function

Bedrest helps in maintaining adequate blood flow to the kidney. If residual infection is suspected, antibiotic therapy may be needed. In the presence of fluid overload, **diuretics** may be used to increase output with urination. Iron and vitamin supplements may be ordered if anemia develops, and antihypertensives, if high blood pressure accompanies the illness. In order to rest the kidney during the acute phase, decreased **sodium** and protein intake may be recommended. The amount of protein allowed is dependent upon the amount lost in the urine, and the requirements of the individual patient. Sodium limitations depend on the amount of **edema** present. Fluid restrictions are adjusted according to the patient's urinary output and body weight.

An accurate daily record of the patient's weight, fluid intake and urinary output assist in estimating kidney function. The patient must be watched for signs of complications and recurrent infection. As edema is reduced and the urine becomes free of protein and red blood cells, the patient is allowed to increase activity. A woman who has had glomerulonephritis requires special medical attention during **pregnancy**.

Prognosis

In acute glomerulonephritis, symptoms usually subside in two weeks to several months, with 90% of children recovering without complications and adults recovering more slowly. Chronic glomerulonephritis is a disease that tends to progress slowly, so that there are no symptoms until the kidneys can no longer function. The resultant renal failure may require dialysis or kidney transplant.

KEY TERMS

Dialysis—A process of filtering and removing waste products from the bloodstream. Two main types are hemodialysis and peritoneal dialysis. In hemodialysis, the blood flows out of the body into a machine that filters out the waste products and routes the cleansed blood back into the body. In peritoneal dialysis, the cleansing occurs inside the body. Dialysis fluid is injected into the peritoneal cavity and wastes are filtered through the peritoneum, the thin membrane that surrounds the abdominal organs.

Glomeruli—Groups of tiny blood vessels with very thin walls that function as filters in the kidney. Glomeruli become inflamed and are destroyed in the disease process of glomerulonephritis.

Renal—Relating to the kidneys, from the Latin word *renes*.

Prevention

Prevention of glomerulonephritis is best accomplished by avoiding upper respiratory infections, as well as other acute and chronic infections, especially those of a streptococcal origin. Cultures of the infection site, usually the throat, should be obtained and antibiotic sensibility of the offending organism determined. Prompt medical assessment for necessary antibiotic therapy should be sought when infection is suspected. The use of prophylactic immunizations is recommended as appropriate.

Glucose-6-phosphate dehydrogenase deficiency

Definition

Glucose-6-phosphate dehydrogenase deficiency is an inherited condition caused by a defect or defects in the gene that codes for the enzyme, glucose-6-phosphate dehydrogenase (G6PD). It can cause **hemolytic anemia**, varying in severity from life-long anemia, to rare bouts of anemia to total unawareness of the condition. The episodes of hemolytic anemia are usually triggered by oxidants, infection, or by eating fava beans.

Description

G6PD deficiency is the most common enzyme deficiency in the world, with about 400 million people living with it. It is most prevalent in people of African, Mediterranean, and Asian ancestry. The incidence in different populations varies from zero in South American Indians to less than 0.1% of Northern Europeans to about 50% of Kurdish males. In the United States, it is most common among African American males; about 11 to 14% are G6PD-deficient.

G6PD deficiency is a recessive sex-linked trait. Thus, males have only one copy of the G6PD gene, but females have two copies. Recessive genes are masked in the presence of a gene that encodes normal G6PD. Accordingly, females with one copy of the gene for G6PD deficiency are usually normal, while males with one copy have the trait.

G6PD is present in all human cells but is particularly important to red blood cells. It is required to make NADPH in red blood cells but not in other cells. It is also required to make glutathione. Glutathione and NADPH both help protect red blood cells against oxidative damage. Thus, when G6PD is defective, oxidative damage to red blood cells readily occurs, and they break open as a result. This event is called hemolysis, and multiple hemolyses in a short time span constitute an episode of hemolytic anemia.

There are almost 100 different known forms of G6PD enzyme molecules encoded by defective G6PD genes, yet not one of them is completely inactive. This suggests that G6PD is indispensable. Many G6PD defective enzymes are deficient in their stability rather than their initial ability to function. Since red blood cells lack nuclei, they, unlike other cells, cannot synthesize new enzyme molecules to replace defective ones. Hence, we expect young red blood cells to have new, functional G6PD and older cells to have nonfunctioning G6PD. This explains why episodes of hemolytic anemia are frequently self-limiting; new red blood cells are generated with enzymes able to afford protection from oxidation.

The geographic distribution of G6PD deficiency, allowing for migration, coincides with the geographic distribution of **malaria**. This fact and survival statistics suggest that G6PD deficiency protects against malaria.

Glucose-6-phosphate dehydrogenase deficiency is also known as G6PD deficiency, favism, and primaquine sensitivity.

Causes and symptoms

Causes

G6PD deficiency is caused by one copy of a defective G6PD gene in males or two copies of a defective G6PD gene in females. Hemolytic anemic attacks can be caused by oxidants, infection, and or by eating fava beans.

Symptoms

The most significant consequence of this disorder is hemolytic anemia, which is usually episodic, but the vast majority of people with G6PD deficiency have no symptoms.

The many different forms of G6PD deficiency have been divided into five classes according to severity.

- Class 1–enzyme deficiency with chronic hemolytic anemia
- Class 2–severe enzyme deficiency with less than 10% of normal activity
- Class 3–moderate to mild enzyme deficiency with 10–60% of normal activity
- Class 4–very mild or no enzyme deficiency
- Class 5–increased enzyme activity

The major symptoms of hemolytic anemia are **jaundice**, dark urine, abdominal **pain**, back pain, lowered red blood cell count, and elevated bilirubin. People who suffer from severe and chronic forms of G6PD deficiency in addition may have **gallstones**, enlarged spleens, defective white blood cells, and **cataracts**.

Attacks of hemolytic anemia are serious for infants. Brain damage and death are possible but preventable outcomes. Newborns with G6PD deficiency

KEY TERMS

Bilirubin—A breakdown product derived from hemoglobin; removed from the blood by the liver.

Enzyme—A protein catalyst; one of the two kinds of biological catalysts, which are exceedingly specific; each different enzyme only catalyzes one or two specific reactions.

Enzyme activity—A measure of the ability of an enzyme to catalyze a specific reaction.

Glutathione—A molecule that acts as a co-enzyme in cellular oxidation-reduction reactions.

Hemolysis—Lysis (opening) of red blood cells, with concomitant leakage of cell contents from the cells.

Hemolytic anemia—Anemia due to hemolysis.

Jaundice—Yellowish skin color due to liver disease.

Neonatal—Describes babies just after they are born.

Recessive trait—An inherited trait that is outwardly obvious only when two copies of the gene for that trait are present—as opposed to a dominant trait where one copy of the gene for the dominant trait is sufficient to display the trait. The recessive condition is said to be masked by the presence of the dominant gene when both are present; i.e., the recessive condition is seen only in the absence of the dominant gene.

Sex-linked—Refers to genes or traits carried on one of the sex chromosomes, usually the X.

X chromosome—One of the two types of sex chromosomes, present twice in female cells and once in male cells.

are about 1.5 times as likely to get **neonatal jaundice** than newborns without G6PD deficiency.

Diagnosis

Blood tests can detect G6PD deficiency, either by measuring the G6PD enzyme activity between episodes or by measuring bilirubin during an episode. Such tests cost about $50.00. Family histories are helpful, too.

Treatment

In a typical attack of hemolytic anemia, no treatment is needed; the patient will recover in about eight days. However, blood transfusions are necessary in severe cases. Recent success treating elevated bilirubin in newborns by exposing them to bright light has decreased the need for neonatal transfusions.

Alternatives

Vitamin E and **folic acid** (both anti-oxidants) may help decrease hemolysis in G6PD-deficient individuals.

Prognosis

The prognosis for almost everyone with G6PD deficiency is excellent. Large studies have shown that G6PD-deficient individuals do not acquire any illnesses more frequently than the rest of the population. In fact the opposite may be true for some diseases like ischemic **heart disease** and cerebrovascular disease.

Prevention

Most episodes of hemolytic anemia can be prevented by avoiding fava beans, oxidant drugs, and oxidant chemicals. All of the following oxidants can trigger attacks: acetanilid, dapsone, doxorubicin, furazolidone, methylene blue, nalidixic acid, napthalene, niridazole, nitrofurantoin, phenazopyridine, phenylhydrazine, primaquine, quinidine, quinine, sulfacetamide, sulfamethoxazole, sulfonamide, sulfapyridine, thiazolesulfone, toluidine blue, and trinitrotoluene. Since infections also trigger hemolytic attacks and have other dire consequences, sometimes it is advisable to use one of the listed drugs.

It is especially important to screen newborns who are likely to have G6PD deficiency to ensure that G6PD-deficient babies won't be subjected to any of the triggers of hemolytic anemia. Pregnant women, especially in areas where G6PD deficiency is prevalent, should avoid eating fava beans.

Gluten-free diet

Definition

A gluten-free diet is a diet that is completely free of gluten, a generic name for a type of storage protein found in certain grains. A gluten-free diet is the prescribed medical treatment for people with gluten intolerance diseases such as **celiac disease** (also referred to as celiac sprue).

Purpose

Gluten-free diets are used by individuals who are sensitive to gluten to prevent damage to their small intestines and to prevent serious complications such as gastrointestinal cancers, iron-deficiency anemia, and decreased bone mineral density. The gluten-free diet is recognized by the medical community as the recommended treatment for individuals exhibiting gluten sensitivity.

Gluten-free diets may also be useful in treating other conditions. Research continues on the benefits of a gluten-free diet for individuals with **multiple sclerosis** and other **autoimmune disorders**, as well as for individuals with **autism** spectrum disorders, **attention deficit hyperactivity disorder (ADHD)**, and some behavioral problems.

Description

Origins

Guidelines for a gluten-free diet were developed by dietitians for several organizations associated with celiac disease and **dermatitis** herpetiformis, including the Gluten Intolerance Group, the Celiac Sprue Association, and the Celiac Disease Foundation. The Academy of

Gluten-free diet

Ingredients/foods to avoid	May contain gluten	Foods allowed
Barley	Baking powder	Amaranth
Bran (wheat or oat)	Beans, baked	Beans, dried, unprocessed
Bulgur	Bouillon cubes	Buckwheat
Cake meal	Candy	Cassava
Couscous	Cheese sauces and spreads	Cheese, aged
Emulsifier	Chips, potato and tortilla	Corn
Farina	Chocolate drinks and mixes	Eggs, unprocessed
Flavoring	Coffee substitutes	Fish, unprocessed
Flour, enriched, durum, graham, semolina	Cold cuts	Flax
Gluten	Communion wafers	Fruits and juices, fresh, frozen or canned
Hydrolyzed plant protein	Corn cakes, popped	Herbs and spices, pure
Kamut	Egg substitutes, dried eggs	Ketchup
Malt and malt flavoring	French fries	Legumes
Matzo meal	Fruits, dried	Meats, unprocessed
Oatmeal and oat bran	Fruit-flavored drinks	Milk
Oats, rolled	Fruit pie fillings	Millet
Rye	Gravy	Mustard
Semolina	Hot dogs and other processed meats	Nuts, unprocessed, and nut flours
Seitan	Matzo	Olives
Soy sauce or soy sauce solids	Mayonnaise	Pickles, plain
Soy	Milk drinks	Potatoes and sweet potatoes
Spelt	Nuts, dry roasted	Quinoa
Stablizer	Peanut butter	Rice, wild rice, Indian rice
Starch, modified, or modified food starch	Pudding mixes	Sago
Triticale	Rice, brown	Seeds, unprocessed
Vegetable gum	Rice crackers and cakes	Soy flour
Vegetable protein	Rice mixes	Soy sauce, gluten-free
Vinegar, malt	Salad dressings	Sorghum
Wheat	Sauces	Tapioca
Wheat berries	Seasoning mixes	Tomato paste
Wheat bran	Sour cream	Vegetables without gluten-containing additives
Wheat, cracked	Soy nuts	Vinegar, apple, cider, and distilled white
Wheat germ	Syrup	Yucca
Wheat protein and hydrolyzed wheat protein	Teas, flavored and herbal	
Wheat starch	Turkey, self-basting	
Whole wheat	Vegetables in sauces	
	Yogurt, flavored or frozen	

(Table by PreMediaGlobal. © Cengage Learning®.)

Nutrition and Dietetics (formerly the American Dietetic Association) also sponsored the development of a gluten-free diet through a cooperative effort of expert dietitians in celiac disease in Canada and the United States.

Gluten-free **diets** are used to treat and manage gluten intolerance diseases, including celiac disease and dermatitis herpetiformis. Celiac disease is a genetically inherited, chronic digestive disease. People with celiac disease develop an inflammatory immune system response to gluten that results in damage to parts of the small intestine responsible for the absorption of nutrients.

Celiac and related diseases

Celiac disease affects about 1% of people in the United States. Another million Europeans are affected. The highest rate of celiac disease is thought to be in Ireland and Finland, and celiac disease is most prevalent among people of Northern European ancestry, where wheat is a staple food. It is found infrequently among people of Chinese and Japanese heritage and individuals with an African-Caribbean background, where wheat is less widely consumed. Incidence of celiac disease has been increasing in India and the Middle East, but the rate is still considered low.

Some individuals with celiac disease also develop dermatitis herpetiformis, an itchy and blistering skin condition. Dermatitis herpetiformis is often a complication of gluten sensitivity. Approximately 20% of individuals with celiac disease have dermatitis herpetiformis, but about 90% of individuals with dermatitis herpetiformis have a gluten sensitivity, indicated by intestinal damage found on **endoscopy**.

When a person with celiac disease or gluten sensitivity consumes gluten, the villi of the small intestine—where absorption of key nutrients takes place—become damaged, resulting in nutrients passing through the digestive system without being absorbed. Symptoms include gastrointestinal distress and eventually **malnutrition**. In infancy, celiac disease can cause **failure to thrive**, **diarrhea**, abdominal distention, developmental delay, and, in some infants, severe malnutrition.

After infancy, the symptoms of celiac disease are less dramatic. Older children may be short statured or exhibit dental enamel defects. Adult women are diagnosed with celiac disease about twice as often as men. Symptoms of celiac disease include diarrhea and/or **constipation**, intestinal gas, fatty and foul-smelling stools, bloating, nausea, **vomiting**, skin irritation, weight loss, anemia, neurological effects (including seizures and possibly migraine headaches), **fatigue**, and concentration and memory problems. In some cases, there may be intestinal damage without significant gastrointestinal symptoms. To control symptoms of gluten intolerance, affected individuals must completely avoid foods that contain gluten.

Celiac disease is diagnosed by blood tests for certain antibodies and a **small intestine biopsy**. A positive small intestine biopsy, followed by an improvement in health after following a gluten-free diet, is confirmation of celiac disease. Since celiac disease is an inherited autoimmune disease, screening of family members is recommended. The chances of developing symptoms of gluten-sensitivity increases to 10–20% in individuals who have a first-degree relative (parent, sibling, child) with celiac disease. Celiac disease is also associated with other autoimmune syndromes such as type 1 diabetes.

Gluten sensitivity

Some individuals may exhibit gluten sensitivity with less obvious gastrointestinal symptoms, but intestinal damage is still seen in a small intestine biopsy. As of 2014, gluten sensitivity was thought by many physicians to be a spectrum disorder, with celiac disease being considered the highest level of gluten intolerance. A less intense response to gluten is difficult to diagnose, but it may be confirmed by having the patient follow a gluten-free diet, followed by reintroduction of gluten-containing foods, to evaluate any health changes associated with the elimination or reduction of gluten from the diet. Some individuals with gluten sensitivity are able to tolerate a low-gluten diet under the supervision of a physician or dietitian. There is no standard agreement on the appropriate level of gluten intake for individuals exhibiting gluten sensitivity, so a method of trial and error is often necessary.

Gluten-free diet

The foods of concern for individuals with, or susceptible to, celiac disease are the grains that contain the storage proteins prolamin and glutelin (commonly referred to as glutens in wheat), including all varieties of wheat (e.g., durum, spelt, kamut), barley (where the storage proteins are called hordiens), rye (where the storage proteins are called secalins), and any crossbred hybrids (e.g., triticale).

In addition to gluten-containing grains, gluten can be found in a large variety of foods, including:

- soups
- salad dressings

WWW.BOOKBAZ.IR

- processed foods
- candy
- imitation bacon and seafood
- marinades
- processed luncheon meats
- sauces and gravies
- self-basting poultry
- soy sauce or soy sauce solids
- thickeners
- communion wafers
- natural flavorings

Unidentified starches, binders, and fillers in medications, supplements, or **vitamins**, as well as adhesives in stamps and stickers, can also be unsuspected sources of gluten. Playdough, which contains wheat, can be harmful if hands are put on or in the mouth after contact or hands are not washed after play.

OATS. Pure, uncontaminated oats eaten in moderation (about one cup cooked daily) may be safe for individuals with celiac disease. However, oats can become cross-contaminated with grains containing gluten during growth, harvest, transport, storage, or processing. Some individuals with celiac disease who introduce oats to their diet may experience abdominal discomfort, gas, and stool changes until they become accustomed to the increased fiber levels from the oats. Others with celiac disease may exhibit a hypersensitivity to oats and should avoid their consumption. Individuals with celiac disease should consult their healthcare provider or a registered dietitian before including oats in their diet and should have their antibody levels monitored regularly.

ALCOHOL. Most beers are brewed with barley or wheat, and thus they should not be consumed by a person following a gluten-free diet. Sorghum and buckwheat beers are available but are considered a specialty product. Most distilled forms of alcohol are gluten-free, unless additives and colorings containing gluten have been added. Wines are also usually gluten-free.

GLUTEN-FREE FOODS. Some grains and starches that are allowed in a gluten-free diet include rice, corn, soy, potato (and sweet potato), tapioca, and beans. Lesser-known gluten-free grains include garfava, sorghum, quinoa, millet, arrowroot, amaranth, teff, nut flours, and buckwheat—though some commercial buckwheat products are mixtures of wheat and buckwheat flours and should be avoided. Other foods that are allowed include fruits; vegetables; cow's milk; aged cheeses; unprocessed meats, poultry, and fish; eggs; dried beans; and nuts and seeds.

Many companies produce gluten-free counterparts to foods that ordinarily contain gluten, such as baking mixes and cereals. Gluten-free foods can be found in health food stores, through mail-order sources, and in some supermarkets. Cookbooks are available to help in food preparation. Many food manufacturers maintain lists of gluten-free products. A dietitian should be consulted to develop and monitor a gluten-free diet.

Gluten-free certification

Several organizations have established gluten-free certification programs to help consumers with celiac disease find gluten-free products. The U.S. Food and Drug Administration (FDA) allows manufacturers to label foods as gluten free if they contain less than 20 parts-per-million (ppm) of gluten, the level considered safe for people with celiac disease to consume. Most certification programs, however, set their limits at 10 ppm or less. Certification generally includes ingredient review, on-site inspection, product testing, and ongoing compliance, which is assessed by annual review. Certifying organizations include the Gluten-Free Certification Organization (GFCO), the Celiac Sprue Association (CSA), and the National Foundation for Celiac Awareness. Approved products display the logo or seal of the certifying organization on their packaging.

Results

A gluten-free diet has been shown to greatly reduce the risk for cancer and overall mortality for individuals with symptomatic celiac disease.

For many people with celiac disease, following a gluten-free diet will stop the symptoms of the disease and result in improved health, usually within several months, although recovery may take up to one year. However, the health of some people with extensive damage to their small intestine may not improve. Refractory celiac disease (RCD), a type of celiac disease that fails to respond to treatment, is a rare syndrome with a poor prognosis. RCD is defined by malabsorption due to gluten-related intestinal damage after initial or subsequent failure of a strict gluten-free diet and after exclusion of any other disease or disorder mimicking celiac disease. Other treatments may be necessary to treat RCD, such as the use of **corticosteroids** and **immunosuppressant drugs**, but data on their effectiveness is lacking.

Precautions

Gluten-free recommendations can be difficult to follow. An individual following a gluten-free diet must read labels every time a food item is purchased or consumed. It is recommended that an affected person keeps the diet simple at the beginning by eating fresh fruits and vegetables, milk, unprocessed protein foods such as fresh beef, pork, poultry, fish, and eggs, natural nuts, seeds, and vegetable oils without additives.

Sometimes it may not be obvious that a product contains gluten. Ingredients that may contain hidden sources of gluten include unidentified starch, modified food starch, hydrolyzed vegetable or plant protein (HVP or HPP), texturized vegetable protein (TVP), and binders, fillers, and extenders. In addition, manufacturers can change ingredients at any time, and a product may no longer be gluten-free. Ingredients may be verified by contacting a manufacturer and specifying the ingredient and lot number of a food item. If a person cannot verify ingredients in a food product or if the ingredient list is unavailable, the food should not be eaten to avoid the damage to the small intestine that occurs every time gluten is consumed.

Some seemingly gluten-free foods may still contain gluten by way of cross-contamination, even if gluten is not indicated on the ingredient list. For example, a conveyer belt may be dusted with a gluten-containing material to prevent foods from sticking, which may contaminate the finished food product.

Risks

A gluten-free diet is difficult to follow, and continued health problems usually are associated with problems adhering to the diet. A person can exhibit celiac-related symptoms for months after even a very small intake of gluten. Individuals with gluten-sensitivity who do not treat their disease are at a higher risk for gastrointestinal T-cell lymphoma and other gastrointestinal cancers. However, the maintenance of a long-term gluten-free state reduces the risk of lymphoma to the level seen in the general population. Other complications of gluten sensitivity include decreased mineral bone density and iron deficiency. Individuals with celiac disease and dermatitis herpetiformis must maintain a gluten-free diet for the rest of their lives, as the diseases cannot be cured.

Individuals are more likely to adhere to the diet if a dietitian and support groups are involved. If a person is not responding well to a gluten-free diet, the doctor may:

- investigate whether the initial diagnosis of celiac disease was correct
- check for other conditions that can be causing symptoms, such as pancreatic insufficiency, irritable bowel syndrome, bacterial overgrowth, lymphocytic colitis, T-cell lymphoma, fructose intolerance, or tropical sprue
- refer the person to a dietitian to check for errors in the diet or for compliance with the diet

To monitor dietary adherence to the gluten-free diet, the dietitian will examine the person's dietary history and habits. Blood tests will be conducted to see if gluten antibody levels have returned to normal levels. If there is clinical concern that a person is not adhering to the gluten-free diet or that the diet is not effective, a biopsy of the small intestine may be conducted.

Gluten-free diets are complex, and it cannot be assumed that chefs in restaurants or others who prepare food (including friends and family) are aware of all of the potential sources for gluten contamination. Education of family and friends is important in accomplishing a lifestyle change. In restaurants, simple dishes without sauces should be ordered, and customers should inquire whether grain products are prepared with the same equipment or utensils used to prepare other foods. Although a food may meet the standards required to be labeled gluten-free, it may be contaminated with gluten by the way in which it was prepared or stored. Other potential challenges associated with following a gluten-free diet include travel, where dietary needs may be difficult to accommodate; finding gluten-free foods, especially those of good quality; determining whether foods are gluten-free; not being invited out or not wanting to go out because of the diet; and maintaining a gluten-free diet when in the hospital, although a clinical dietitian should be able to assist in accommodating dietary needs.

As with any restrictive diet, a gluten-free diet has potential for nutritional inadequacy. Individuals who are sensitive to gluten are at increased risk for **osteoporosis** and osteomalacia due to malabsorption of **calcium** and **vitamin D**. Calcium and vitamin D supplementation along with strict adherence to a gluten-free diet usually results in remineralization of the skeleton. However, iron or other vitamin deficiencies may also be present and must be treated appropriately. The consumption of gluten-free, fiber-rich foods (e.g., brown rice, fruits, and vegetables) and adequate fluid intake is recommended to assist in the prevention of constipation.

Women with untreated celiac disease often exhibit a history of miscarriages, anemia, low-birthweight babies, and unfavorable **pregnancy** outcomes. It is

KEY TERMS

Anemia—A condition in which there are too few red blood cells, too many abnormal red blood cells, or too little iron-containing hemoglobin for normal oxygen transport in the body.

Attention deficit hyperactivity disorder (ADHD)—A learning and behavioral disorder characterized by difficulty in sustaining attention, impulsive behavior, and excessive activity.

Autoimmunity—A condition in which the body's immune system produces antibodies in response to its own tissues or blood components instead of foreign particles or microorganisms.

Corticosteroids—Medication that acts like a type of hormone (cortisol) produced by the adrenal gland of the body. As a drug, a corticosteroid (sometimes just called steroid) provides extra cortisol, which helps treat infection or trauma to the body.

Immunosuppressant—Any agent that decreases the immune response of an individual.

Osteomalacia—A softening of bones caused by a lack of vitamin D and/or calcium in the diet.

Osteoporosis—A condition more common in older individuals in which bones decrease in density and become fragile and more likely to break. It can be caused by lack of vitamin D and/or calcium in the diet.

Type 1 diabetes—A chronic immune system disorder in which the pancreas does not produce sufficient amounts of insulin, a hormone that enables cells to use glucose (sugar) for energy. Formerly called juvenile diabetes, it must be treated with insulin injections and is sometimes referred to as insulin-dependent diabetes.

suggested that testing for celiac disease be included in the battery of tests prescribed for pregnant women. Celiac disease is considerably more common than most of the diseases for which pregnant women are routinely screened.

Research and general acceptance

The National Institutes of Health has noted that the strict definition of a gluten-free diet remains controversial due to the lack of an accurate method to detect gluten in food products and the lack of scientific evidence for what constitutes a safe amount of gluten ingestion. No international agreement has yet been developed on how much gluten a person with gluten sensitivity can tolerate, and this amount likely falls on a spectrum for individual people. Research is ongoing to better identify levels that are acceptable, and health professionals involved in the therapy of celiac disease should keep up-to-date on the latest research. On January 23, 2007, the FDA proposed to set a standard of 20 parts per million as the maximum acceptable level of gluten allowed for a product to be labeled as gluten-free. Labeling is voluntary. European standards for labeling a food gluten-free are more strict than those in the United States.

In addition, a new enzyme that was being developed for commercial food processing has been found to break down gluten molecules quickly and almost completely. The enzyme is made from *Aspergillus niger*, a common fungus that is the source of other food grade enzymes already being manufactured for human consumption. Fritz Koning of Leiden University Medical Center in the Netherlands was leading the research as of early 2012. He stated that if the enzyme proves itself in clinical trials to eliminate the need for a gluten-free diet, it could be mass produced at a reasonable cost.

Glycogen storage diseases

Definition

Glycogen serves as the primary fuel reserve for the body's energy needs. Glycogen storage diseases, also known as glycogenoses, are genetically linked metabolic disorders that involve the enzymes regulating glycogen metabolism. Symptoms vary by the glycogen storage disease (GSD) type and can include **muscle cramps** and wasting, enlarged liver, and low blood sugar. Disruption of glycogen metabolism also affects other biochemical pathways as the body seeks alternative fuel sources. Accumulation of abnormal metabolic by-products can damage the kidneys and other organs. GSD can be fatal, but the risk hinges on the type of GSD.

Description

Most of the body's cells rely on glucose as an energy source. Glucose levels in the blood are very stringently controlled within a range or 70–100 mg/dL, primarily by hormones such as insulin and glucagon. Immediately after a meal, blood glucose levels rise and exceed the body's immediate energy requirements.

WWW.BOOKBAZ.IR

In a process analogous to putting money in the bank, the body bundles up the extra glucose and stores it as glycogen in the liver and muscles. Later, as the blood glucose levels begin to dip, the body makes a withdrawal from its glycogen savings.

The system for glycogen metabolism relies on a complex system of enzymes. These enzymes are responsible for creating glycogen from glucose, transporting the glycogen to and from storage areas within cells, and extracting glucose from the glycogen as needed. Both creating and tearing down the glycogen macromolecule are multistep processes requiring a different enzyme at each step. If one of these enzymes is defective and fails to complete its step, the process halts. Such enzyme defects are the underlying cause of GSDs.

The enzyme defect arises from an error in its gene. Since the error is in the genetic code, GSDs can be passed down from generation-to-generation. However, all but one GSD are linked to autosomal genes, which means a person inherits one copy of the gene from each parent. Following a Mendelian inheritance pattern, the normal gene is dominant and the defective gene is recessive. As long as a child receives at least one normal gene, there is no risk for a GSD. GSDs appear only if a person inherits a defective gene from both parents.

The most common forms of GSD are Types I, II, III, and IV, which may account for more than 90% of all cases. The most common form is Type I, or von Gierke's disease, which occurs in one out of every 100,000 births. Other forms, such as Types VI and IX, are so rare that reliable statistics are not available. The overall frequency of all forms of glycogen storage disease is approximately one in 20,000–25,000 live births.

Causes and symptoms

GSD symptoms depend on the enzyme affected. Since glycogen storage occurs mainly in muscles and the liver, those sites display the most prominent symptoms.

There are at least 10 different types of GSDs which are classified according to the enzyme affected:

- Type Ia, or von Gierke's disease, is caused by glucose-6-phosphatase deficiency in the liver, kidney, and small intestine. The last step in glycogenolysis, the breaking down of glycogen to glucose, is the transformation of glucose-6-phosphate to glucose. In GSD I, that step does not occur. As a result, the liver is clogged with excess glycogen and becomes enlarged and fatty. Other symptoms include low blood sugar and elevated levels of lactate, lipids, and uric acid in the blood. Growth is impaired, puberty is often delayed, and bones may be weakened by osteoporosis. Blood platelets are also affected and frequent nosebleeds and easy bruising are common. Primary symptoms improve with age, but after age 20–30, liver tumors, liver cancer, chronic renal disease, and gout may appear.
- Type Ib is caused by glucose-6-phosphatase translocase deficiency. In order to carry out the final step of glycogenolysis, glucose-6-phosphate has to be transported into a cell's endoplasmic reticulum. If translocase, the enzyme responsible for that movement, is missing or defective, the same symptoms occur as in Type Ia. Additionally, the immune system is weakened and victims are susceptible to bacterial infections, such as pneumonia, mouth and gum infections, and inflammatory bowel disease. Types Ic and Id are also caused by defects in the translocase system.
- Type II, or Pompe's disease or acid maltase deficiency, is caused by lysosomal alpha-D-glucosidase deficiency in skeletal and heart muscles. GSD II is subdivided according to the age of onset. In the infantile form, infants seem normal at birth, but within a few months they develop muscle weakness, trouble breathing, and an enlarged heart. Cardiac failure and death usually occur before age 2, despite medical treatment. The juvenile and adult forms of GSD II affect mainly the skeletal muscles in the body's limbs and torso. Unlike the infantile form, treatment can extend life, but there is no cure. Respiratory failure is the primary cause of death.
- Type III, or Cori's disease, is caused by glycogen debrancher enzyme deficiency in the liver, muscles, and some blood cells, such as leukocytes and erythrocytes. About 15% of GSD III cases only involve the liver. The glycogen molecule is not a simple straight chain of linked glucose molecules, but rather an intricate network of short chains that branch off from one another. In glycogenolysis, a particular enzyme is required to unlink the branch points. When that enzyme fails, symptoms similar to GSD I occur; in childhood, it may be difficult to distinguish the two GSDs by symptoms alone. In addition to the low blood sugar, retarded growth, and enlarged liver causing a swollen abdomen, GSD III also causes muscles prone to wasting, an enlarged heart, and heightened levels of lipids in the blood. The muscle wasting increases with age, but the other symptoms become less severe.
- Type IV, or Andersen's disease, is caused by glycogen brancher enzyme deficiency in the liver, brain, heart, skeletal muscles, and skin fibroblasts. The glycogen constructed in GSD IV is abnormal and

KEY TERMS

Amniocentesis—A medical test done during pregnancy in which a small sample of the amniotic fluid is taken from around the fetus. The fluid contains fetal cells that can be examined for genetic abnormalities.

Autosomal gene—A gene found on one of the 22 autosomal chromosome pairs; i.e., not on a sex (X or Y) chromosome.

Chorionic villus sampling—A medical test done during pregnancy in which a sample of the membrane surrounding the fetus is removed for examination. This examination can reveal genetic fetal abnormalities.

Glucose—A form of sugar that serves as the body's main energy source.

Glycogen—A macromolecule composed mainly of glucose that serves as the storage form of glucose that is not immediately needed by the body.

Glycogenolysis—The process of tearing-down a glycogen molecule to free up glucose.

Glycogenosis—An alternate term for glycogen storage disease. The plural form is glycogenoses.

Gout—A painful condition in which uric acid precipitates from the blood and accumulates in joints and connective tissues.

Mendelian inheritance—An inheritance pattern for autosomal gene pairs. The genetic trait displayed results from one parent's gene dominating over the gene inherited from the other parent.

Osteoporosis—A disease in which the bones become weak and brittle.

Renal disease—Kidney disease.

Transgenic animal—Animals that have had genes from other species inserted into their genetic code.

insoluble. As it accumulates in the cells, cell death leads to organ damage. Infants born with GSD IV appear normal at birth, but are diagnosed with enlarged livers and failure to thrive within their first year. Infants who survive beyond their first birthday develop cirrhosis of the liver by age 3–5 and die as a result of chronic liver failure.

- Type V, or McArdle's disease, is caused by glycogen phosphorylase deficiency in skeletal muscles. Under normal circumstances, muscles cells rely on oxidation of fatty acids during rest or light activity. More demanding activity requires that they draw on their glycogen stockpile. In GSD V, this form of glycogenolysis is disabled and glucose is not available. The main symptoms are muscle weakness and cramping brought on by exercise, as well as burgundy-colored urine after exercise due to myoglobin (a breakdown product of muscle) in the urine.
- Type VI, or Hers' disease, is caused by liver phosphorylase deficiency, which blocks the first step of glycogenolysis. In contrast to other GSDs, Type VI seems to be linked to the X chromosome. Low blood sugar is one of the key symptoms, but it is not as severe as in some other forms of GSD. An enlarged liver and mildly retarded growth also occur.
- Type VII, or Tarui's disease, is caused by muscle phosphofructokinase deficiency. Although glucose may be available as a fuel in muscles, the cells cannot metabolize it. Therefore, abnormally high levels of glycogen are stockpiled in the muscle cells. The symptoms are similar to GSD V, but also include anemia and increased levels of uric acid.
- Types VIII and XI are caused by defects of enzymes in the liver phosphorylase activating-deactivating cascade and have symptoms similar to GSD VI.
- Type IX is caused by liver glycogen phosphorylase kinase deficiency and, symptom-wise, is very similar to GSD VI. The main differences are that the symptoms may not be as severe and may also include exercise-related problems in the muscles, such as pain and cramps. The symptoms abate after puberty with proper treatment. Most cases of GSD IX are linked to the X chromosome and therefore affect males.
- Type X is caused by a defect in the cyclic adenosine monophosphate-dependent (AMP) kinase enzyme and presents symptoms similar to GSDs VI and IX.

Diagnosis

Diagnosis usually occurs in infancy or childhood, although some milder types of GSD go unnoticed well into adulthood and old age. It is even conceivable that some of the milder GSDs are never diagnosed.

The four major symptoms that typically lead a doctor to suspect GSDs are low blood sugar, enlarged liver, retarded growth, and an abnormal blood **biochemistry** profile. A definitive diagnosis is obtained by biopsy of the affected organ or organs. The biopsy sample is tested for its glycogen content and assayed for enzyme activity. There are DNA-based techniques for diagnosing some

WWW.BOOKBAZ.IR

GSDs from more easily available samples, such as blood or skin. These DNA techniques can also be used for prenatal testing.

Treatment

Some GSD types cannot be treated, while others are relatively easy to control through symptom management. In more severe cases, receiving an organ transplant is the only option. In the most severe cases, there are no available treatments and the victim dies within the first few years of life.

Of the treatable types of GSD, many are treated by manipulating the diet. The key to managing GSD I is to maintain consistent levels of blood glucose through a combination of nocturnal intragastric feeding (usually for infants and children), frequent high-carbohydrate meals during the day, and regular oral doses of cornstarch (people over age 2). Juvenile and adult forms of GSD II can be managed somewhat by a high protein diet, which also helps in cases of GSD III, GSD VI, and GSD IX. GSD V and GSD VII can also be managed with a high protein diet and by avoiding strenuous **exercise**.

For GSD cases in which dietary therapy is ineffective, organ transplantation may be the only viable alternative. Liver transplants have been effective in reversing the symptoms of GSD IV.

Advances in genetic therapy offer hope for effective treatment in the future. This therapy involves using viruses to deliver a correct form of the gene to affected cells.

Prognosis

People with well-managed, treatable types of GSD can lead long, relatively normal lives. This goal is accomplished with the milder types of GSD, such as Types VI, IX, and X. As the GSD type becomes more severe, a greater level of vigilance against infections and other complications is required. Given current treatment options, complications such as **liver disease**, **heart failure**, and **respiratory failure** may not be warded-off indefinitely. Quality of life and life expectancy are substantially decreased.

Prevention

Because GSD is an inherited condition, it is not preventable. If both parents carry the defective gene, there is a one-in-four chance that their offspring will inherit the disorder. Other children may be carriers or they may miss inheriting the gene altogether.

Through chorionic villi sampling and **amniocentesis**, the disorder can be detected prior to birth. Some types of GSD can be detected even before conception occurs, if both parents are tested for the presence of the defective gene. Before undergoing such testing, the prospective parents should meet with a genetic counselor and other professionals in order to make an informed decision.

Glycosylated hemoglobin test

Definition

Glycosylated hemoglobin is a test that indicates how much sugar has been in a person's blood during the past two to four months. It is used to monitor the effectiveness of diabetes treatment.

Purpose

Diabetes is a disease in which a person cannot effectively use sugar in the blood. Left untreated, blood sugar levels can be very high. High sugar levels increase risk of complications, such as damage to eyes, kidneys, heart, nerves, blood vessels, and other organs.

A routine blood sugar test reveals how close to normal a sugar level is at the time of the test. The glycosylated **hemoglobin test** reveals how close to normal it has been during the past several months.

This information helps a physician evaluate how well a person is responding to diabetes treatment and to determine how long sugar levels have been high in a person newly diagnosed with diabetes.

Description

The Diabetes Control and Complications Trial (DCCT) demonstrated that people with diabetes who

maintained blood glucose (sugar) and total fasting hemoglobin levels at or close to a normal range decreased their risk of complications by 50–75%. Based on results of this study, the American Diabetes Association (ADA) recommends routine glycosylated hemoglobin testing to measure long-term control of blood sugar.

Glycosylated hemoglobin measures the percentage of hemoglobin bound to glucose. Hemoglobin is a protein found in every red blood cell. As hemoglobin and glucose are together in the red blood cell, the glucose gradually binds to the A1c form of hemoglobin in a process called glycosylation. The amount bound reflects how much glucose has been in the blood during the past average 120-day lifespan of red cells.

Several methods are used to measure the amount of bound hemoglobin and glucose. They are electrophoresis, chromatography, and immunoassay. All are based on the separation of hemoglobin bound to glucose from that without glucose.

The ADA recommends glycosylated hemoglobin be done during a person's first diabetes evaluation, again after treatment is begun and sugar levels are stabilized, then repeated at least semiannually. If the person does not meet treatment goals or sugar levels have not stabilized, the test should be repeated quarterly.

Other names for the test include: Hemoglobin A1c, HbA1c, Diabetic control index, GHb, glycosylated hemoglobin, and glycated hemoglobin. The test is covered by insurance. Results usually are available the following day.

Preparation

A person does not need to fast before this test. A healthcare worker ties a tourniquet on the person's upper arm, locates a vein in the inner elbow region, and inserts a needle into the vein. Vacuum action draws the blood through the needle into an attached tube. Collection of the sample takes only a few minutes. This test requires 5 mL of blood.

While home HbA1c tests are available, they should only be used with a doctor's guidance.

Aftercare

Discomfort or bruising may occur at the puncture site, or the person may feel dizzy or faint. Pressure to the puncture site until bleeding stops reduces bruising. Warm packs relieve discomfort.

KEY TERMS

Diabetes mellitus—A disease in which a person can't effectively use sugar in the blood to meet the needs of the body. It is caused by a lack of the hormone insulin.

Glucose—The main form of sugar used by the body for energy.

Glycosylated hemoglobin—A test that measures the amount of hemoglobin bound to glucose. It is a measure of how much glucose has been in the blood during the past two to four months.

Results

Diabetes treatment should achieve glycosylated hemoglobin levels of less than 7.0%. Normal value for a non-diabetic person is 4.0–6.0%.

Because laboratories use different methods, results from different laboratories can not always be compared. The National Glycosylation Standardization Program gives a certification to laboratories using tests standardized to those used in the DCCT study.

Abnormal

Results require interpretation by a physician with knowledge of the person's clinical condition, as well as the test method used. Some methods give false high or low results if the person has an abnormal hemoglobin, such as hemoglobin S or F.

Conditions that increase the lifespan of red cells, such as a **splenectomy** (removal of the spleen), falsely increase levels. Conditions that decrease the lifespan, such as hemolysis (disruption of the red blood cell membrane), falsely decrease levels.

Goiter

Definition

Goiter refers to any visible enlargement of the thyroid gland.

Description

The thyroid gland sits astride the trachea (windpipe) and is shaped like a butterfly. It makes thyroxin, a hormone that regulates the metabolic activity of the body, rather like the gas pedal on a car. Too much thyroxin increases the metabolism, causing weight loss, temperature elevation, nervousness, and irritability. Too little thyroxin slows the metabolism down, deepens the voice, causes weight gain and water retention, and retards growth and mental development in children. Both conditions also alter hair and skin growth, bowel function, and menstrual flow.

This woman's goiter may have been caused by an insufficient intake of iodine. *(Custom Medical Stock Photo, Inc.)*

Curiously, the thyroid gland is often enlarged whether it is making too much hormone, too little, or sometimes even when it is functioning normally. The thyroid is controlled by the pituitary gland, which secretes thyroid stimulating hormone (TSH) in response to the amount of thyroxin it finds in the blood. TSH increases the amount of thyroxin secreted by the thyroid and also causes the thyroid gland to grow.

- Hyperthyroid goiter—If the amount of stimulating hormone is excessive, the thyroid will both enlarge and secrete too much thyroxin. The result—hyperthyroidism with a goiter. Graves' disease is the most common form of this disorder.
- Euthyroid goiter—The thyroid is the only organ in the body to use iodine. If dietary iodine is slightly inadequate, too little thyroxin will be secreted, and the pituitary will sense the deficiency and produce more TSH. The thyroid gland will enlarge enough to make sufficient thyroxin.
- Hypothyroid goiter—If dietary iodine is severely reduced, even an enlarged gland will not be able to make enough thyroxin. The gland will keep growing under the influence of TSH, but it may never be able to make enough thyroxin.

Causes and symptoms

Excess TSH (or similar hormones), cysts, and tumors will enlarge the thyroid gland. Of these, TSH enlarges the entire gland while cysts and tumors enlarge only a part of it.

The only symptom from a goiter is the large swelling just above the breast bone. Rarely, it may constrict the trachea (windpipe) or esophagus and cause difficulty breathing or swallowing. The rest of the symptoms come from thyroxin or the lack of it.

Diagnosis

The size, shape, and texture of the thyroid gland help the physician determine the cause. A battery of blood tests are required to verify the specific thyroid disease. Functional imaging studies using radioactive iodine determine how active the gland is and what it looks like.

Treatment

Goiters of all types will regress with treatment of the underlying condition. Dietary iodine may be all that is needed. However, if an iodine deficient thyroid that has grown in size to accommodate its deficiency is suddenly supplied an adequate amount of iodine, it could suddenly make large amounts of thyroxin and

KEY TERMS

Cyst—A liquid-filled structure developing abnormally in the body.

Euthyroid—Having the right amount of thyroxin stimulation.

Hyperthyroid—Having too much thyroxin stimulation.

Hypothyroid—Having too little thyroxin stimulation.

Pituitary gland—The master gland, located in the middle of the head, that controls most of the other glandss by secreting stimulating hormones.

Radiotherapy—The use of ionizing radiation, either as x rays or radioactive isotopes, to treat disease.

Thyroxin—The hormone secreted by the thyroid gland.

cause a thyroid storm, the equivalent of racing your car motor at top speed.

Hyperthyroidism can be treated with medications, therapeutic doses of radioactive iodine, or surgical reduction. Surgery is much less common now than it used to be because of progress in drugs and radiotherapy.

Prognosis

Although goiters diminish in size, the thyroid may not return to normal. Sometimes thyroid function does not return after treatment, but thyroxin is easy to take as a pill.

Prevention

Euthyroid goiter and hypothyroid goiter are common around the world because many regions have inadequate dietary iodine, including some places in the United States. International relief groups are providing iodized salt to many of these populations. Because **intellectual disability** (ID) is a common result of **hypothyroidism** in children, this is an extremely important project.

Gonadal dysgenesis *see* **Turner syndrome**

Gonorrhea

Definition

Gonorrhea is a highly contagious sexually transmitted infection (STI) or disease (STD) caused by the bacterium *Neisseria gonorrhoeae*. These bacteria grow in the urethra and in warm, moist parts of the reproductive tract, including the cervix, uterus, and fallopian tubes of women. The bacteria also can infect the anus, mouth, throat, and eyes. Untreated gonorrhea can cause serious medical complications.

Demographics

For most of the twentieth century gonorrhea was the most common STD worldwide. The incidence of gonorrhea has declined steadily in the developed world since the mid-1970s, reaching an all-time low in 2004. This decline is largely due to increased public awareness of the risks and prevention of STDs such as herpes and HIV/AIDS. However there are still about 200 million new cases of gonorrhea annually throughout the world and gonorrhea rates in certain urban areas of the United States are once again on the rise.

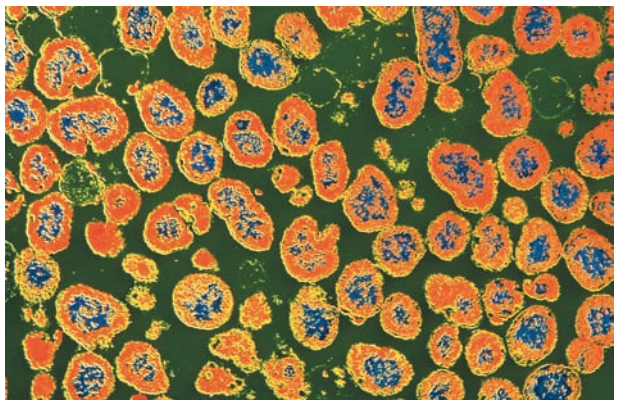
Gonorrhea is the second most common reportable disease in the United States. More than 350,000 newly diagnosed cases were reported in 2007. Experts believe that the actual number is much higher since gonorrhea tends to be both under-diagnosed and underreported. Estimates of the actual number of annual cases in the United States range from 400,000 to one million. An estimated 40,000 pregnant women are infected with gonorrhea each year in the United States. **Pelvic inflammatory disease** (PID), the most common complication of gonorrhea, affects one million American women annually.

Although gonorrhea affects people of all ages, races, and socioeconomic levels, adolescents and young adults are at the highest risk. More than 80% of cases occur in those aged 15 to 29. Gonorrhea is most common among females aged 15–19 and males aged 20–24. Infection rates are higher in men than in women and highest in men who have sex with other men. African Americans and those living in urban areas and having multiple sex partners are at the greatest risk for infection.

Description

Commonly called "the clap," gonorrhea is transmitted through sexual contact, including oral, anal,

WWW.BOOKBAZ.IR



A transmission electron microscopy (TEM) image of *Neisseria gonorrhoeae*. *(Custom Medical Stock Photo, Inc.)*

and vaginal intercourse. The risk of contracting gonorrhea from a single sexual encounter with an infected partner is 60–90%. Gonorrhea also can be spread through contact with the bodily fluids of an infected person. There is some evidence for transmission of gonorrhea among children and from adults to children via unclean hands. However gonorrhea infection in children is considered a warning flag for **sexual abuse**.

Gonorrhea usually affects the genitourinary tract, but can also spread to the rectum, throat, and eyes. Left untreated, gonorrhea can spread through the bloodstream and infect the reproductive system, joints, heart valves, skin, liver, and brain. As many as 10% of women infected with gonorrhea experience a **pregnancy** in a fallopian tube (**ectopic pregnancy**) or become infertile as a result of PID. Gonorrhea also increases the risk of contracting and transmitting HIV/AIDS. Being cured of gonorrhea does not protect a person against re-infection.

Pregnant women with untreated gonorrhea are at increased risk for **miscarriage**, preterm birth, or membranes that rupture prematurely. An infected mother can transmit the disease to her infant as it passes through the birth canal during delivery, causing newborn conjunctivitis—an eye infection that can lead to blindness. The infant also is at risk for joint infection or a life-threatening blood infection.

Risk factors

Risk factors for gonorrhea are similar to those for other STDs. The primary risk factors are unprotected sex (without a condom) with multiple partners.

Causes and symptoms

Gonnorrhea is caused by the bacterium *N. gonorrhoeae*, which is transmitted through sexual contact. It can be transmitted to the eyes by touching an infected organ and then touching the eyes. *N. gonorrhoeae* cannot survive for any length of time outside of the human body. It cannot be transmitted via a toilet seat or by shaking hands.

Although most gonorrhea-infected males have symptoms, as many as 80% of infected females do not. Symptoms usually appear between one and 14 days following infection, but the incubation period can be as long as 30 days. Often the only symptom of gonorrhea is inflammation of mucous membranes in the genital region. Some people experience nausea, **vomiting**, **fever**, and chills, and **pain** during intercourse.

In males the infection usually appears first in the urethra—the tube that carries urine and sperm to the outside of the body. About 95% of infected men have thick, cloudy, white, yellowish, green, or bloody discharge from the penis. Other common symptoms in males include frequent urination and burning or pain during urination. Complications of gonorrhea in males can affect the prostate, testicles, and surrounding glands. **Epididymitis** is a painful condition of the testicles that can lead to sterility if untreated.

In females gonorrhea usually infects the cervix—the lower narrow portion of the uterus that opens to the vagina—as well as the uterus and fallopian tubes. Symptoms can include:

- vaginal discharge that may be cloudy and yellow
- frequent, painful, or burning urination
- bleeding between menstrual periods
- pain or bleeding during vaginal intercourse
- heavy bleeding during menstrual periods
- chronic abdominal pain

Women are more likely than men to suffer from complications of gonorrhea because the disease often progresses without symptoms. The most common complication of untreated gonorrhea is PID, which can occur in as many as 40% of infected women. PID can damage the ovaries and fallopian tubes, resulting in a pregnancy developing outside of the uterus or sterility. A less common complication is disseminated gonococcal infection (DGI), in which the bacteria travels through the blood to distant sites such as the skin or joints.

KEY TERMS

Cervix—The lower, narrow part—or neck—of the uterus.

Chlamydia—The most common sexually transmitted bacterial infection in the United States. It often occurs along with gonorrhea. The majority of infected women have no symptoms.

Conjunctivitis—An inflammation of the eye that can be caused by gonorrhea or chlamydia.

Ectopic pregnancy—A pregnancy that develops outside of the uterus, such as in the fallopian tubes. The fetus dies and the mother's life may be threatened.

ELISA—Enzyme-linked immunosorbent assay; a screening test that uses antibodies to detect infections such as gonorrhea and HIV.

HIV/AIDS—Human immunodeficiency virus/acquired immunodeficiency syndrome; a sexually transmitted viral disease that is more likely to be transmitted or acquired in the presence of gonorrhea or another STD.

Neisseria gonorrhoeae—The bacterium that causes gonorrhea.

Nucleic acid amplification test (NAAT)—A screening test for gonorrhea that detects bacterial DNA in a urine sample or cervical swab.

Pelvic inflammatory disease (PID)—An infection of the female upper genital tract that can be a complication of gonorrhea. At least 25% of women with PID suffer long-term consequences such as infertility or an ectopic pregnancy.

Sexually transmitted disease (STD)—A disease that is transmitted by sexual contact, including gonorrhea, chlamydia, HIV/AIDS, genital herpes, syphilis, and genital warts.

Sexually transmitted infection (STI)—An infectious disease, such as gonorrhea, that is transmitted through sexual activity.

Sterility—Inability to conceive a child.

Urethra—The urine channel leading from the bladder to the outside of the body and, in men, the channel for semen.

Urethritis—Inflammation of the urethra.

Newborn **conjunctivitis** caused by gonorrhea usually appears two–seven days after birth. Symptoms of eye infection include redness, **itching**, or discharge from the eye. Other symptoms of gonorrhea in infants and children include irritation, redness, swelling, or a pus-like discharge from the urethra and possibly painful urination.

Anal gonorrheal infection may cause rectal itching, discharge, a constant urge to move the bowels, painful bowel movements, or blood in the stool. However about 90% of anal infections are without symptoms. Oral gonorrheal infection may cause a **sore throat** or painful swallowing.

Diagnosis

Examination

An initial diagnosis of gonorrhea is based on symptoms, sexual history, and at-risk behavior. The diagnosis may be made by a family physician or STD specialist or at a **public health** clinic. Women may be diagnosed by an obstetrician/gynecologist, particularly if there are gynecological complications. Men may be diagnosed by a urologist. Physicians are required to report cases of gonorrhea to public health officials. Patients are asked to provide the names of all sexual partners who may have been exposed to the infection, so that they can be notified and tested for gonorrhea.

Tests

Many physicians use more than one test to confirm a diagnosis of gonorrhea:

- A nucleic acid amplifications test (NAAT) that detects bacterial DNA in a urine or cervical sample is the fastest and most accurate diagnostic test.
- An enzyme-linked immunosorbent assay (ELISA) that uses antibodies specific for *N. gonorrhoeae* is also fast and sensitive.
- Culturing bacteria from a discharge or sample obtained with a cotton swab can diagnose gonorrhea and determine whether the bacteria are drug resistant. Culturing takes for up to two days.
- Discharge from an infected area can Gram stained and examined under a microscope for the presence of *N. gonorrhoeae*; however this test is only about 70% accurate in men and about 50% accurate in women.
- Since other STDs, such as chlamydia and syphilis, often occur along with gonorrhea, patients also may be tested for these infections.

WWW.BOOKBAZ.IR

Treatment

Gonorrhea is treated with **antibiotics**. Patients should refrain from sexual intercourse until they and their partners have completed treatment and had follow-up testing to ensure that the infection has been completely eradicated.

Drugs

In the past gonorrhea was usually treated with penicillin, a penicillin derivative, or tetracycline. However since the 1940s *N. gonorrhoeae* has become increasingly resistant to these antibiotics. Resistance to fluoroquinolone antibiotics also has increased rapidly over the past decade. Therefore currently, the recommended treatments for gonorrhea are:

- a single 125-mg injection of ceftriaxone
- a single 400-mg dose of oral cefixime
- another single-dose cephalosporin antibiotic

Infants born to gonorrhea-infected mothers may be treated with intravenous ceftriaxone or another antibiotic. Infant conjunctivitis caused by gonorrhea is treated with an eye ointment containing polymyxin and bacitracin, erythromycin, or tetracycline.

If chlamydial infection is also present, a combination of antibiotics—such as ceftriaxone and doxycycline or azithromycin—is used to treat both infections simultaneously. Erythromycin is used to treat chlamydia in pregnant women.

Alternatives

Antibiotic treatment for gonorrhea may be complemented with various alternative therapies:

- *Lactobacillus acidophilus* or live-culture yogurt can help replace gastrointestinal flora that are killed by the antibiotics.
- Zinc, multivitamin/mineral complexes, vitamin C, and garlic (*Allium sativum*) may help improve immune system function.
- Kelp (*Macrocystis pyrifera* and related species) can supply vitamins and minerals.
- Teas or douches made with calendula (*Calendula officinalis*), myrrh (*Commiphora molmol*), and thuja (*Thuja occidentalis*) may reduce discharge and inflammation.
- The Chinese herb *Coptis chinensis*, used for "damp-heat;" infections, can be helpful for treating the genitourinary tract, especially if PID develops.
- Various other herbs can help treat reproductive and urinary system symptoms.
- With physician approval, a three-day juice fast may help cleanse the urinary and gastrointestinal systems and support healing.
- Acupuncture or acupressure can help cleanse body systems.

Antibiotic treatment is absolutely essential for gonorrhea. Hot baths can help reduce pain and inflammation.

Prognosis

Gonorrhea is curable with cephalosporin antibiotics and the prognosis is excellent with prompt treatment. However many people, especially women, have no symptoms of the disease and are unaware that they are infected. Adolescent girls are at particular risk for untreated gonorrhea. Up to 40% of women who do not receive early treatment may develop PID, which can damage the fallopian tubes and result in sterility. Women who have had PID are six–ten times more likely to have an ectopic pregnancy. Although the risk of **infertility** is higher for women than for men, men also can become sterile if untreated gonorrhea causes inflammation of the urethra (**urethritis**).

Untreated gonorrhea can cause inflammation, abscesses, and scarring. In about 2% of patients with untreated gonorrhea, the infection spreads throughout the body, causing fever, arthritis-like joint pain, and **skin lesions**. The bacterium also can infect the heart valves and brain. In men, untreated gonorrhea can affect the prostate, testicles, and surrounding glands.

Prevention

The best prevention for gonorrhea is sexual abstinence or sexual activity that is confined to a mutually monogamous relationship in which both partners have been tested for gonorrhea and other STDs. If used properly and consistently for vaginal and anal sex, latex male **condoms** and polyurethane female condoms can reduce the risk of *N. gonorrhoeae* transmission. A dental dam may reduce the risk of transmission during oral sex. However anyone who has multiple sexual partners should be tested regularly for gonorrhea and other STDs. It is recommended that all sexually active teenagers and young adults be screened regularly for gonorrhea. All pregnant women should be screened at their first prenatal visit.

All newborns are treated under the eyelids with an antibiotic ointment, such as silver nitrate or erythromycin, to prevent gonorrhea. Infants born to mothers with untreated gonorrhea are given a prophylactic dose of ceftriaxone.

Margaret Alic, PhD

Goodpasture's syndrome

Definition

An uncommon and life-threatening hypersensitivity disorder believed to be an autoimmune process related to antibody formation in the body. Goodpasture's syndrome is characterized by renal (kidney) disease and lung hemorrhage.

Demographics

Goodpasture's syndrome is a rare autoimmune disorder, with a predominance in young males typically between the ages of 20 and 30 years. It occurs more often in African Americans than Caucasians, and has also been observed in the Maori ethnic group of New Zealand.

Risk factors

There are no known risk factors for Goodpasture's syndrome however in some cases, affected individuals have been known to be ill with an upper respiratory tract infection before the development of the disorder. There may also be a connection between substances such as hydrocarbon solvents and some chemicals found in certain weed killers, however, the exact cause of Goodpasture's syndrome remains unknown.

Description

The disorder is characterized by an autoimmune reaction which deposits antibodies in the membranes of both the lung and kidneys, causing both inflammation of kidney (**glomerulonephritis**) and lung bleeding.

Causes and symptoms

The exact cause is unknown. It is an autoimmune disorder; that is, the immune system is fighting the body's own normal tissues through creating antibodies that attack the lungs and kidneys. Sometimes the disorder is triggered by a viral infection, or by the

WWW.BOOKBAZ.IR

inhalation of gasoline or other hydrocarbon solvents. An association also exists between cigarette **smoking** and the syndrome. The target antigen of the Goodpasture's antibodies has been localized to a protein chain (type IV collagen).

Symptoms include foamy, bloody, or dark colored urine, decreased urine output, **cough** with bloody sputum, difficulty breathing after exertion, weakness, **fatigue**, nausea or **vomiting**, weight loss, nonspecific chest **pain** and/or pale skin.

Diagnosis

The clinician will perform a battery of tests to confirm a diagnosis. These tests include a **complete blood count** (CBC) to confirm anemia, iron levels to check for blood loss and blood urea nitrogen (BUN) and creatinine levels to test the kidney function. A **urinalysis** will be done to check for damage to the kidneys. A sputum test will be done to look for specific antibodies. A chest x ray will be done to assess the amount of fluid in the lung tissues. A lung needle biopsy and a **kidney biopsy** will show immune system deposits. The kidney biopsy can also show the presence of the harmful antibodies that attack the lungs and kidneys.

Treatment

Treatment is focused on slowing the progression of the disease. Treatment is most effective when begun early, before kidney function has deteriorated to a point where the kidney is permanently damaged, and dialysis is necessary. **Corticosteroids**, such as prednisone, or other anti-inflammatory medications may be used to reduce the immune response. Immune suppressants such as cyclophosphamide or azathioprine are used aggressively to reduce immune system effects.

A procedure whereby blood plasma, which contains antibodies, is removed from the body and replaced with fluids or donated plasma (**plasmapheresis**) may be performed daily for two or more weeks to remove circulating antibodies. It is fairly effective in slowing or reversing the disorder. Dialysis to clean the blood of wastes may be required if kidney function is poor. A kidney transplant may be successful, especially if performed after circulating antibodies have been absent for several months.

Prognosis

The probable outcome is variable. Most cases progress to severe renal failure and end-stage renal disease within months. Early diagnosis and treatment makes the probable outcome more favorable.

KEY TERMS

Antibody—A protein molecule produced by the immune system in response to a protein that is not recognized as belonging in the body.

Antigen—Any substance that, as a result of coming in contact with appropriate cells, induces a state of sensitivity and/or immune responsiveness after a period of time and that reacts in a demonstrable way with antibodies.

Autoimmune disorder—An abnormality within the body whereby the immune system incorrectly attacks the body's normal tissues, thereby causing disease or organ dysfunction.

Blood urea nitrogen (BUN)—A test used to measure the blood level of urea nitrogen, a waste that is normally filtered from the kidneys.

Creatinine—A test used to measure the blood level of creatinine, a waste product filtered out of the blood by the kidneys. Higher than usual levels of this substance may indicate kidney disease.

Glomerulus (glomeruli)—A small tuft of blood capillaries in the kidney, responsible for filtering out waste products.

Prevention

No known prevention of Goodpasture's syndrome exists. Smoking cessation can reduce further damage to the lungs. Early diagnosis and treatment may slow progression of the disorder.

REVISED BY LAURA JEAN CATALDO, RN, EdD

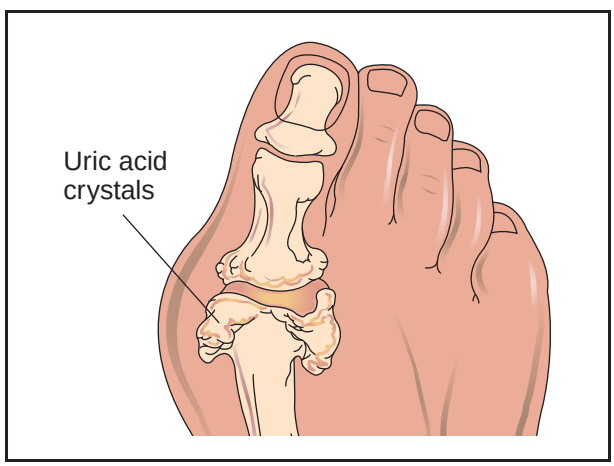
Gout

Definition

Gout is a form of acute arthritis that causes severe **pain** and swelling in the joints. It most commonly affects the big toe, but may also affect the heel, ankle, hand, wrist, or elbow. It affects the spine often enough to be a factor in back pain. Gout usually comes on suddenly, goes away after 5–10 days, and can keep recurring. Gout is different from other forms of arthritis because it occurs when there are high levels of uric acid circulating in the blood, which can cause urate crystals to settle in the tissues of the joints.

Description

Uric acid, which is found naturally in the bloodstream, is formed as the body breaks down waste products, mainly those containing purine, a substance that is produced by the body and is also found in high concentrations in some foods, including brains, liver, sardines, anchovies, and dried peas and beans. Normally, the kidneys filter uric acid out of the blood and excrete it in the urine. Sometimes, however, the body produces too much uric acid or the kidneys are not efficient enough at filtering it from the blood, and it builds up in the bloodstream, a condition known as hyperuricemia. A person's susceptibility to gout may increase because of the inheritance of certain genes or from being overweight and eating a rich diet. In some cases, another disease (such as lymphoma, leukemia, or **hemolytic anemia**) may be the underlying cause of the uric acid buildup that results in gout. An additional factor is occupational or environmental; it is now known that chronic exposure to high levels of lead decreases the body's excretion of urates, allowing uric acid to accumulate in the blood.



Gout, a form of acute arthritis, most commonly occurs in the big toe. It is caused by high levels of uric acid in the blood, in which urate crystals settle in the tissues of the joints and produce severe pain and swelling. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Hyperuricemia does not always cause gout. Over the course of years, however, sharp urate crystals build up in the synovial fluid of the joints. Often, some precipitating event, such as an infection, surgery, the **stress** of hospitalization, a stubbed toe, or even a heavy drinking binge can cause inflammation. White blood cells, mistaking the urate crystals for a foreign invader, flood into the joint and surround the crystals, causing inflammation—in other words, the redness, swelling, and pain that are the hallmarks of a gout attack.

Causes and symptoms

As a result of high levels of uric acid in the blood, needle-like urate crystals gradually accumulate in the joints. Urate crystals may be present in the joint for a long time without causing symptoms. Infection, injury to the joint, surgery, drinking too much, or eating the wrong kinds of foods may suddenly bring on the symptoms, which include pain, tenderness, redness, warmth, and swelling of the joint. In many cases, the gout attack begins in the middle of the night. The pain is often so excruciating that the sufferer cannot bear weight on the joint or tolerate the pressure of bedcovers. The inflamed skin over the joint may be red, shiny, and dry, and the inflammation may be accompanied by a mild **fever**. These symptoms may go away in about a week and disappear for months or years at a time. However, over the course of time, attacks of gout recur more and more frequently, last longer, and affect more joints. Eventually, stone-like deposits known as tophi may build up in the joints, ligaments, and tendons, leading to permanent joint deformity and decreased motion. (In addition to causing the tophi associated with gout, hyperuricemia can also cause **kidney stones**, also called renal calculi or uroliths.)

Gout affects an estimated one million Americans; according to the National Institutes of Health, it accounts for about 5% of all cases of arthritis. It

WWW.BOOKBAZ.IR

occurs more often in men than in women; the sex ratio is about 4:1. Uric-acid levels tend to increase in men at **puberty**, and, because it takes 20 years of hyperuricemia to cause gout symptoms, men commonly develop gout in their late 30s or early 40s. Women more typically develop gout later in life, starting in their 60s. According to some medical experts, estrogen protects against hyperuricemia, and when estrogen levels fall during **menopause**, urate crystals can begin to build up in the joints. Excess body weight, regular excessive alcohol intake, the use of blood pressure medications called **diuretics**, and high levels of certain fatty substances in the blood (serum **triglycerides**) associated with an increased risk of **heart disease** can all increase a person's risk of developing gout.

Gout appears to be on the increase in the American population. According to a study published in November 2002, there was a twofold increase in the incidence of gout over the 20 years between 1977 and 1997. It is not yet known whether this increase is the result of improved diagnosis or whether it is associated with risk factors that have not yet been identified.

Diagnosis

Usually, physicians can diagnose gout based on the **physical examination** and medical history (the patient's description of symptoms and other information). Doctors can also administer a test that measures the level of uric acid in the blood. While normal uric acid levels don't necessarily rule out gout and high levels don't confirm it, the presence of hyperuricemia increases the likelihood of gout. The development of a tophus can confirm the diagnosis of gout. The most definitive way to diagnose gout is to take a sample of fluid from the joint and test it for urate crystals.

Treatment

The goals of treatment for gout consist of alleviating pain, avoiding severe attacks in the future, and preventing long-term joint damage. In addition to taking pain medications as prescribed by their doctors, people having gout attacks are encouraged to rest and to increase the amount of fluids that they drink.

Acute attacks of gout can be treated with nonaspirin, **nonsteroidal anti-inflammatory drugs** (NSAIDs) such as naproxen **sodium** (Aleve), ibuprofen (Advil), or indomethacin (Indocin). In some cases, these drugs can aggravate a peptic ulcer or existing **kidney disease** and cannot be used. Doctors may also use colchicine (Colbenemid), especially in cases where nonsteroidal anti-inflammatory drugs cannot be used. Colchicine may cause **diarrhea**, which tends to go away once the patient stops taking it. **Corticosteroids** such as prednisone (Deltasone) and adrenocorticotropic hormone (Acthar) may be given orally or may be injected directly into the joint for a more concentrated effect. While all of these drugs have the potential to cause side effects, they are used for only about 48 hours and are not likely to cause major problems. However, **aspirin** and closely related drugs (salicylates) should be avoided because they can ultimately worsen gout.

Once an acute attack has been successfully treated, doctors try to prevent future attacks of gout and long-term joint damage by lowering uric acid levels in the blood. There are two types of drugs for correcting hyperuricemia. Such uricosuric drugs as probenecid (Benemid) and sulfinpyrazone (Anturane) lower the levels of urate in the blood by increasing its removal from the body (excretion) through the urine. These drugs may promote the formation of kidney stones, however, and they may not work for all patients, especially those with kidney disease. Allopurinol (Zyloprim), a type of drug called a xanthine-oxidase

KEY TERMS

Allopurinol—A drug that corrects hyperuricemia by inhibiting urate production.

Colchicine—A drug used to treat painful flare-ups of gout.

Corticosteroids—Medications related to a natural body hormone called hydrocortisone, which are used to treat inflammation.

Hyperuricemia—High levels of a waste product called uric acid in the blood.

Probenecid—A drug that corrects hyperuricemia by increasing the urinary excretion of urate.

Purine—A substance found in foods that is broken down into urate and may contribute to hyperuricemia and gout.

Sulfinpyrazone—A drug that corrects hyperuricemia by increasing the urinary excretion of urate.

Synovial fluid—Fluid surrounding the joints which acts as a lubricant, reducing the friction between the joints.

Tophus (plural, tophi)—A chalky deposit of a uric acid compound found in gout. Tophi occur most frequently around joints and in the external ear.

Urate crystals—Crystals formed by high levels of uric acid in the blood.

inhibitor, blocks the production of urate in the body, and can dissolve kidney stones as well as treating gout. The potential side effects of allopurinol include rash, a skin condition known as **dermatitis**, and liver dysfunction. In 2004, the FDA was seeking trial data on a new drug called oxypurinol (Oxyprim) for treating chronic gout. These medications may have to be taken for life to prevent further gout attacks.

Alternatives

Alternative approaches to gout focus on correcting hyperuricemia by encouraging weight loss and limiting the intake of alcohol and purine-rich foods. In addition, consuming garlic (*Allium sativum*) has been recommended to help prevent gout. Increasing fluid intake, especially by drinking water, is also recommended. During an acute attack, contrast **hydrotherapy** (alternating three-minute hot compresses with 30–second cold compresses) can help dissolve the crystals and resolve the pain faster.

Prognosis

Gout cannot be cured but usually it can be managed successfully. As tophi dissolve, joint mobility generally improves. (In some cases, however, medicines alone do not dissolve the tophi and they must be removed surgically.) Lowering uric acid in the blood also helps to prevent or improve the kidney problems that may accompany gout.

Prevention

For centuries, gout has been known as a "rich man's disease" or a disease caused by overindulgence in food and drink. While this view is perhaps a little overstated and oversimplified, lifestyle factors clearly influence a person's risk of developing gout. Since **obesity** and excessive alcohol intake are associated with hyperuricemia and gout, losing weight and limiting alcohol intake can help ward off gout. **Dehydration** may also promote the formation of urate crystals, so people taking diuretics or "water pills" may be better off switching to another type of blood pressure medication. Everyone should be sure to drink at least six to eight glasses of water each day. Since purine is broken down in the body into urate, it may also be helpful to avoid foods high in purine, such as organ meats, sardines, anchovies, red meat, gravies, beans, beer, and wine. A 2004 study revealed that eating more low-fat dairy products could reduce risk of developing gout.

Gout drugs

Definition

Gout drugs are medicines that prevent or relieve the symptoms of gout, a disease that affects the joints and kidneys.

Purpose

Gout is a disease in which uric acid, a waste product that normally passes out of the body in urine, collects and forms crystals in the joints and the kidneys. When uric acid crystals build up in the joints, the tissue around the joint becomes inflamed, and nerve endings in the area become irritated, causing extreme **pain**. Uric acid crystals in the kidneys can lead to **kidney stones** and eventually to kidney failure.

The symptoms of gout—severe pain, usually in the hand or foot (often at the base of the big toe), but sometimes in the elbow or knee—should be

WWW.BOOKBAZ.IR

reported to a healthcare professional. If not treated, gout can lead to high blood presssure, deformed joints, and even death from kidney failure. Fortunately, the condition is easily treated. For patients who have just had their first attack, physicians may prescribe only medicine to reduce the pain and inflammatin, such as **nonsteroidal anti-inflammatory drugs**, **corticosteroids**, or colchicine. Patients may also be advised to change their eating and drinking habits, avoiding organ meats and other protein-rich foods, cutting out alcoholic beverages, and drinking more water. Some people never have another gout attack after the first. For those who do, physicians may prescribe additional drugs that either help the body get rid of uric acid or reduce the amount of uric acid the body produces. These drugs will not relieve gout attacks that already have started, but will help prevent attacks when taken regularly.

Description

Three main types of drugs are used in treating gout. Colchicine helps relieve the symptoms of gout by reducing inflammation. Allopurinol (Lopurin, Zyloprim) reduces the amount of uric acid produced in the body. Probenecid (Benemid, Probalan) and sulfinpyrazone (Anturane) help the body get rid of excess uric acid. Physicians may recommend that patients take more than one type of gout drug at the same time. Some of these medicines may also be prescribed for other medical conditions that are caused by too much uric acid in the body.

Recommended dosage

The recommended dosage depends on the type of gout drug. Check with the physician who prescribed the drug or the pharmacist who filled the prescription for the correct dosage.

Always take gout drugs exactly as directed. Never take larger or more frequent doses than recommended. Patients who are told to take more than one gout drug should carefully follow the physician's directions for taking all medicines.

Gout drugs such as allopurinol, probenecid, and sulfinpyrazone must be taken regularly to prevent gout attacks. The medicine may take some time to begin working, so gout attacks may continuee for awhile after starting to take the drug. Continuing to take the drug is important, even if it does not seem to be working at first.

Colchicine may be taken regularly in low doses to help prevent gout attacks or in high doses for only a few hours at a time to relieve an attack. The chance of serious side effects is greater when this medicine is taken in high doses for short periods.

Precautions

Seeing a physician regularly while taking gout drugs is important. The physician will check to make sure the medicine is working as it should and will watch for unwanted side effects. Blood tests may be ordered to help the physician monitor how well the drug is working.

Drinking alcohol, including beer and wine, may increase the amount of uric acid in the body and may interfere with the effects of gout medicine. People with gout (or other conditions that result from excess uric acid) may need to limit the amount of alcohol they drink or stop drinking alcohol altogether.

Some people feel drowsy or less alert when taking gout drugs. Anyone who takes this type of medicine should not drive, use machines or do anything else that might be dangerous until they have found out how the drugs affect them.

Some gout drugs may change the results of certain medical tests. Before having medical tests, anyone taking this medicine should alert the healthcare professional in charge.

Older people may be especially sensitive to the effects of colchicine. The drug may also stay in their bodies longer than it does in younger people. Both the increased sensitivity to the drug and the longer time for the drug to leave the body may increase the chance of side effects.

Special conditions

People who have certain medical conditions or who are taking certain other medicines can have problems if they take gout drugs. Before taking these drugs, be sure to let the physician know about any of these conditions:

ALLERGIES. Anyone who has ever had unusual reactions to gout drugs or to medicines used to relieve pain or inflammation should let his or her physician know before taking gout drugs. The physician should also be told about any **allergies** to foods, dyes, preservatives, or other substances.

DIABETES. Some gout drugs may cause false results on certain urine sugar tests, but not on others. Diabetic patients who take gout drugs should check with their physicians to find out if their medicine will affect the results of their urine sugar tests.

PREGNANCY. The effects of taking gout drugs during **pregnancy** are not fully understood. Women who

are pregnant or who may become pregnant should check with their physicians before using gout drugs.

BREASTFEEDING. Gout drugs may pass into breast milk. Women who are taking this medicine and want to breastfeed their babies should check with their physicians.

OTHER MEDICAL CONDITIONS. Gout drugs may cause problems for people with certain medical conditions. For example, the risk of severe allergic reactions or other serious side effects is greater when people with these medical conditions take certain gout drugs:

- congestive heart disease
- high blood pressure
- blood disease
- diabetes
- kidney disease or kidney stones
- cancer being treated with drugs or radiation
- stomach or intestinal problems, including stomach ulcer (now or in the past)

Before using gout drugs, people with any of medical problems listed above should make sure their physicians are aware of their conditions.

USE OF CERTAIN MEDICINES. Taking gout drugs with certain other drugs may affect the way the drugs work or may increase the chance of side effects.

Side effects

A skin rash that develops during treatment with gout drugs may be a sign of a serious and possibly life-threatening reaction. If any of these symptoms occur, stop taking the medicine and check with a physician immediately:

- skin rash, itching, or hives
- scaly or peeling skin
- chills, fever, sore throat, nausea and vomiting, yellow skin or eyes, joint pain, muscle aches or pains—especially if these symptoms occur at the same time or shortly after a skin rash

Patients taking colchicine should stop taking it immediately if they have **diarrhea**, stomach pain, nausea, or **vomiting**. If these symptoms continue for 3 hours or more after the medicine is stopped, check with a physician.

Other side effects may also need medical attention. If any of the following symptoms occur while taking gout drugs, check with the physician who prescribed the medicine as soon as possible:

- pain in the side or lower back
- painful urination
- blood in the urine

Less serious side effects, such as **headache**, loss of appetite, and joint pain and inflammation usually go away as the body adjusts to the drug and do not need medical treatment.

Other side effects may occur. Anyone who has unusual symptoms while taking gout drugs should get in touch with his or her physician.

INTERACTIONS. Gout drugs may interact with other medicines. When this happens, the effects of one or both of the drugs may change or the risk of side effects may be greater. Anyone who takes gout drugs should let the physician know all other medicines he or she is taking. Among the drugs that may interact with gout drugs are:

- **Aspirin** or other salicylates. These drugs may keep gout drugs from working properly.
- Nonsteroidal anti-inflammatory drugs such as indomethacin (Indocin) and ketoprofen (Orudis). Taking these medicines with probenecid may increase the chance of side effects from the nonsteroidal anti-inflammatory drugs.
- Blood thinners. When taken with blood thinners, such as warfarin (Coumadin), gout drugs may increase the chance of bleeding. A lower blood thinner dose may be necessary.
- Blood viscosity reducing medicines such as pentoxifylline (Trental). Taking this medicine with blood thinners may increase the chance of bleeding.
- Medicine for infections. Probenecid may increase the levels of these medicines in the blood. This may make the other medicine work better, but may also increase the risk of side effects.
- The immunosuppressant drug azathioprine (Imuran), used to prevent organ rejection in transplant patients and to treat **rheumatoid arthritis**. Taking this medicine with allopurinol can increase the risk of side effects from the azathioprine.
- Anticancer drugs such as mercaptopurine (Purinethol), plicamycin (Mithracin), and methotrexate (Rheumatrex). Taking this medicine with gout drugs may increase the risk of side effects from the anticancer drug.
- Antiretroviral drugs such as zidovudine (Retrovir). Probenecid may increase the level of this medicine in the blood. This may make side effects more likely.
- Antiseizure medicines such as Depakote (divalproex) and Depakene (valproic acid). Using these medicines with sulfinpyrazone may increase the chance of bleeding.

The list above does not include every drug that may interact with gout drugs. Be sure to check with a

WWW.BOOKBAZ.IR

physician or pharmacist before combining gout drugs with any other prescription or nonprescription (over-the-counter) medicine.

Graft-vs.-host disease

Definition

Graft-vs.-host disease is an immune attack on the recipient by cells from a donor.

Description

The main problem with transplanting organs and tissues is that the recipient host does not recognize the new tissue as its own. Instead, it attacks it as foreign in the same way it attacks germs, to destroy it.

If immunogenic cells from the donor are transplanted along with the organ or tissue, they will attack the host, causing graft vs. host disease.

The only transplanted tissues that house enough immune cells to cause graft vs. host disease are the blood and the bone marrow. Blood transfusions are used every day in hospitals for many reasons. Bone marrow transplants are used to replace blood forming cells and immune cells. This is necessary for patients whose cancer treatment has destroyed their own bone marrow. Because bone marrow cells are among the most sensitive to radiation and **chemotherapy**, it often must be destroyed along with the cancer. This is true primarily of leukemias, but some other cancers have also been treated this way.

Causes and symptoms

Even if the donor and recipient are well matched, graft-vs.-host disease can still occur. There are many different elements involved in generating immune reactions, and each person is different, unless they are identical twins. Testing can often find donors who match all the major elements, but there are many minor ones that will always be different. How good a match is found also depends upon the urgency of the need and some good luck.

Blood **transfusion** graft-vs.-host disease affects mostly the blood. Blood cells perform three functions: carrying oxygen, fighting infections, and clotting. All of these cell types are decreased in a transfusion graft-vs.-host reaction, leading to anemia (lack of red blood cells in the blood), a decrease in resistance to infections, and an increase in bleeding. The reaction occurs between four to 30 days after the transfusion.

The tissues most affected by bone marrow graft-vs.-host disease are the skin, the liver, and the intestines. One form or the other occurs in close to half of the patients who receive bone marrow transplants.

Bone marrow graft-vs.-host disease comes in an acute and a chronic form. The acute form appears within two months of the transplant; the chronic form usually appears within three months. The acute disease produces a skin rash, liver abnormalities, and **diarrhea** that can be bloody. The skin rash is primarily a patchy thickening of the skin. Chronic disease can produce a similar skin rash, a tightening or an inflammation of the skin, lesions in the mouth, drying of the eyes and mouth, hair loss, liver damage, lung damage, and **indigestion**. The symptoms are similar to an autoimmune disease called **scleroderma**.

Both forms of graft-vs.-host disease bring with them an increased risk of infections, either because of the process itself or its treatment with cortisone-like drugs and immunosuppressives. Patients can die of liver failure, infection, or other severe disturbances of their system.

Treatment

Both the acute and the chronic disease are treated with cortisone-like drugs, immunosuppressive agents like cyclosporine, or with **antibiotics** and immune chemicals from donated blood (**gamma globulin**). Infection with one particular virus, called cytomegalovirus (CMV) is so likely a complication that some experts recommend treating it ahead of time.

Prognosis

Children with **acute leukemias** have greatly benefited from the treatment made possible by **bone marrow transplantation**. Survival rates have climbed by 15–50%. It is an interesting observation that patients who develop graft-vs.-host disease are less likely to have a recurrence of the leukemia that was being treated. This phenomenon is called graft-vs.-leukemia.

Bone marrow transplant patients who do not have a graft-vs.-host reaction gradually return to normal

KEY TERMS

Anemia—Too few red blood cells, or too little hemoglobin in them.

Immunoglobulin—Chemicals in the blood that defend against infections.

Immunosuppressive—A chemical which suppresses an immune response.

Inflammation—The body's immune reaction to presumed foreign substances like germs. Inflammation is characterized by increased blood supply and activation of defense mechanisms. It produces redness, swelling, heat, and pain.

Lesion—Localized disease or damage.

Scleroderma—Progressive disease of the connective tissue of the skin and internal organs.

immune function in a year. A graft-vs.-host reaction may prolong the diminished immune capacity indefinitely, requiring supplemental treatment with immunoglobulins (gamma globulin).

Somehow the grafted cells develop a tolerance to their new home after six to 12 months, and the medications can be gradually withdrawn. Graft-vs.-host disease is not the only complication of blood transfusion or bone marrow transplantation. Host-vs.-graft or rejection is also common and may require a repeat transplant with another donor organ. Infections are a constant threat in bone marrow transplant because of the disease being treated, the prior radiation or chemotherapy and the medications used to treat the transplant.

Prevention

For recipients of blood transfusions who are especially likely to have graft-vs.-host reactions, the red blood cells can safely be irradiated (using x rays) to kill all the immune cells. The red blood cells are less sensitive to radiation and are not harmed by this treatment.

Much current research is directed towards solving the problem of graft-vs.-host disease. There are efforts to remove the immunogenic cells from the donor tissue, and there are also attempts to extract and purify bone marrow cells from the patient before treating the cancer. These cells are then given back to the patient after treatment has destroyed all that were left behind.

Granuloma inguinale

Definition

Granuloma inguinale is a sexually transmitted infection that affects the skin and mucous membranes of the anal and genital areas. Its name is derived from granuloma, a medical term for a mass or growth of granulation tissue, and *inguinale*, a Latin word that means located in the groin. Granulation tissue is tissue formed during wound healing that is rich in blood capillaries and has a rough or lumpy surface.

Description

Granuloma inguinale is a chronic infection with frequent relapses caused by a rod-shaped bacterium. It occurs worldwide but is most common in tropical or subtropical countries, where it is associated with poverty and poor hygiene. As many as 20% of male patients with sexually transmitted diseases (STDs) in tropical countries have granuloma inguinale. The disease is less common in the United States, with fewer than 100 reported cases per year. Most patients are between the ages of 20 and 40 years, with a 2:1 male-to-female ratio.

Although granuloma inguinale is relatively uncommon in the United States in comparison with other STDs, it is still a significant **public health** problem. It can be acquired through casual sexual contacts when traveling abroad. Moreover, patients with granuloma inguinale are vulnerable to superinfection (infection by other disease agents) with other STDs, especially **syphilis**. Patients with granuloma inguinale are also a

WWW.BOOKBAZ.IR

KEY TERMS

Donovan bodies—Rod-shaped oval organisms found in tissue samples from patients with granuloma inguinale. Donovan bodies appear deep purple when stained with Wright's stain.

Granulation tissue—A kind of tissue formed during wound healing, with a rough or irregular surface and a rich supply of blood capillaries.

Granuloma—An inflammatory swelling or growth composed of granulation tissue, as in granuloma inguinale.

Keloid—An unusual or abnormal growth of scar tissue, as in the third stage of granuloma inguinale.

Punch biopsy—A method of obtaining skin samples under local anesthesia using a surgical skin punch.

Superinfection—A condition in which a patient with a contagious disease acquires a second infection, as when a patient with granuloma inguinale is also infected with syphilis.

Wright's stain—A chemical used to stain tissue samples for laboratory analysis.

high-risk group for Acquired Immune Deficiency Syndrome (**AIDS**) transmission, because the disease causes open genital **ulcers** that can be easily invaded by the AIDS virus.

Granuloma inguinale is spread primarily through heterosexual and male homosexual contact; however, its occurrence in children and sexually inactive adults indicates that it may also be spread by contact with human feces. Granuloma inguinale is not highly contagious; however, persons with weakened immune systems are at greater risk of infection.

Causes and symptoms

Granuloma inguinale, which is sometimes called donovanosis, is caused by *Calymmatobacterium granulomatis*, a rod-shaped bacterium formerly called *Donovania granulomatis*. The bacterium has an incubation period ranging from eight days to 12 weeks, with an average of two to four weeks. The disease has a slow and gradual onset, beginning with an inconspicuous pimple or lumpy eruption on the skin. In 90% of patients, the initial sign of infection is in the genital region, but a minority of patients will develop the sore in their mouth or anal area if their sexual contact involved those parts of the body. Many patients do not notice the sore because it is small and not usually painful. In some women, the first symptom of granuloma inguinale is bleeding from the genitals.

The initial pimple or sore is typically followed by three stages of disease. In the first stage, the patient develops a mass of pink or dull red granulation tissue in the area around the anus. In the second stage, the bacteria erode the skin to form shallow, foul-smelling ulcers which spread from the genital and anal areas to the thighs and lower abdomen. The edges of the ulcers are marked by granulation tissue. In the third stage, the ulcerated areas form deep masses of keloid or scar tissue that may spread slowly for many years.

Patients with long-term infections are at risk for serious complications. The ulcers in second-stage granuloma inguinale often become superinfected with syphilis or other STD organisms. Superinfected ulcers become painful to touch, filled with pus and dead tissue, and are much more difficult to treat. There may be sizable areas of tissue destruction in superinfected patients. In addition, the scar tissue produced by third-stage infection can grow until it closes off parts of the patient's urinary tract. It is also associated with a higher risk of genital cancer.

Diagnosis

The most important aspect of diagnosis is distinguishing between granuloma inguinale and other STDs, particularly since many patients will be infected with more than one STD. Public health officials recommend that patients tested for granuloma inguinale be given a blood test for syphilis as well. In addition, the doctor will need to distinguish between granuloma inguinale and certain types of **skin cancer**, **amebiasis**, **fungal infections**, and other bacterial ulcers. The most significant distinguishing characteristic of granuloma inguinale is the skin ulcer, which is larger than in most other diseases, painless, irregular in shape, and likely to bleed when touched.

The diagnosis of granuloma inguinale is made by finding Donovan bodies in samples of the patient's skin tissue. Donovan bodies are oval rod-shaped organisms that appear inside infected tissue cells under a microscope. The doctor obtains a tissue sample either by

cutting a piece of tissue from the edge of an skin ulcer with a scalpel or by taking a punch biopsy. To make a punch biopsy, the doctor will inject a local anesthetic into an ulcerated area and remove a piece of skin about 1/16 of an inch in size with a surgical skin punch. The tissue sample is then air-dried and stained with Wright's stain, a chemical that will cause the Donovan bodies to show up as dark purple safety pin-shaped objects inside lighter-staining capsules.

Treatment

Granuloma inguinale is treated with oral **antibiotics**. Three weeks of treatment with erythromycin, streptomycin, or tetracycline, or 12 weeks of treatment with ampicillin are standard forms of therapy. Although the skin ulcers will start to show signs of healing in about a week, the patient must take the full course of medication to minimize the possibility of relapse.

Prognosis

Most patients with granuloma inguinale recover completely, although superinfected ulcers may require lengthy courses of medication. Early treatment prevents the complications associated with second- and third-stage infection.

Prevention

Prevention of granuloma inguinale has three important aspects:

- Avoidance of casual sexual contacts, particularly among homosexual males, in countries with high rates of the disease
- Tracing and examination of an infected person's recent sexual contacts
- Monitoring the patient's ulcers or scar tissue for signs of reinfection for a period of six months after antibiotic treatment

Grief counseling

Definition

Grief counseling refers to a specific form of therapy, or a focus in general counseling with the goal of helping the individual grieve and address personal loss in a healthy manner. Grief counseling is offered individually by psychologists, clergy, counselors or social workers, in groups led by professionals, as well as informal support groups offered by churches, community groups, or organizations devoted to helping individuals grieve specific losses.

Purpose

The purpose of grief counseling is to help individuals work through the feelings, thoughts, and memories associated with the loss of a loved one. Although grieving can occur for other types of loss as well (such as loss of goals, ideals, and relationships), grief counseling is generally directed toward positive adjustment following loss after the death of a loved one.

Specific tasks of grief counseling include emotional expression about the loss (which can include a wide range of feelings), accepting the loss, adjusting to life after the loss, and coping with the changes within oneself and the world after the loss. Typical feelings experienced by individuals, and addressed in grief counseling, include sadness, **anxiety**, anger, loneliness, guilt, relief, **isolation**, confusion, or numbness. Behavioral changes may also be noticed, such as being disorganized, feeling tired, having trouble concentrating, sleep problems, appetite changes, vivid dreams, or daydreaming about the deceased.

Grief counseling helps the individual recognize normal aspects of the grieving or mourning process, cope with the **pain** associated with the loss, feel supported through the anxiety surrounding life changes that may follow the loss, and develop strategies for seeking support and self-care.

Description

Grief counseling helps the individual work through the feelings associated with the loss of another, accept that loss, determine how life can go on without that person, and consolidate memories in order to be able to move forward. Grief counseling also provides information about the normal grieving process, to help individuals understand that many of the symptoms and changes they are experiencing are a normal, temporary

WWW.BOOKBAZ.IR

reaction to loss. For some individuals, the primary focus of grief counseling is to help identify ways to express feelings about the loss that the person has been unable to express on his or her own. Individuals who seek grief counseling may be experiencing an emotional numbness, or a residual **shock** in reaction to the loss, and need assistance to return to a normal life. In those cases, grief counseling will focus on helping the individual get in touch with those feelings and become more active in ones daily routine.

For some people, grieving may initially be so extreme that physical and psychological symptoms may be experienced, while other people appear to experience no symptoms whatsoever. Activities of daily living may feel overwhelming to an individual who has experienced a loss. In these cases, grief counseling may focus on specific coping skills to help the individual resume some normalcy in his or her daily routine. For example, if sleep patterns are disrupted, grief counseling may include consultation with the individual's physician to assist with temporary strategies to increase sleep. If the individual is having trouble getting to work on time, behavioral strategies may be used as an interim measure to help the person return to aspects of normal daily life.

Additional work in grief counseling may involve identifying ways to let go or say good–bye if the individual has not been able to do so successfully. Therapeutic letters may be a helpful mechanism to express thoughts that were not conveyed prior to the death. Dreams are frequently experienced by survivors, and these can be a focus in grief counseling as well. The dreams can often be consoling and as well, a way of consolidating the memories about the deceased.

Precautions

Grieving is a normal life process—an adjustment reaction to a loss. Grief counseling is meant to facilitate that normal process. No specific precautions are warranted. However, there are certain circumstances in which complications to the normal grieving process may occur. These circumstances may involve the loss of a child, or the loss of a loved one due to an accident or homicide, for example.

In these cases of complicated grieving, more extreme responses to the loss may be observed, depending on the individual's capacity for coping, personal resiliency, and support system. For example, if the individual feels isolated, he may be at greater risk for severe depressive symptoms or a **suicide** attempt. Alternatively, if the survivors feel rage or anger over the loss, there may be a risk of harm to others.

Preparation

No specific preparation is required by the participant; however, a need for grief counseling is indicated by prolonged symptoms (such as crying spells, preoccupation with the deceased, lack of motivation, or suicidal thoughts), and the severity of personal distress over the loss. A patient seeking grief counseling would most likely undergo a clinical evaluation by a therapist, before the grief counseling began, so that the therapist could understand the patient's personal history and goals for treatment.

Aftercare

Aftercare is usually provided through informal support systems, which may include family and friends, as well as support groups.

Results

Normal results from grief counseling include being able to move on with one's life, recognizing and accepting the physical loss of the individual, and being able to bridge that loss with positive memories of the deceased. Successful coping will be characterized by a return to normal routines, although some symptoms may be experienced periodically throughout the year or on dates of important anniversaries such as a wedding, birthday, or the date of the loss.

Abnormal results would include an unsuccessful outcome of prolonged grief, exhibited by continued preoccupation with the loss of the individual, crying spells, and depressive symptoms being the most likely complications. Some disruption of the daily routine would persist, and there may be extreme emotional responses, that could include no apparent reaction to difficulty containing feelings. Other complications include "unfinished business," or feelings of unresolved issues with the deceased. Sometimes the feelings of unresolved issues can be as simple as wishing they had communicated their love and affection for the person the last time they saw them, or may be as complicated as unresolved feelings about a history of **abuse** by the deceased.

Risks

A slight risk exists regarding treatment of complicated grief. Such circumstances include chronic, prolonged grieving or unexpected loss (particularly due to a violent accident, suicide, homicide, or the death of a

KEY TERMS

Anxiety—Can be experienced as a troubled feeling, a sense of dread, fear of the future, or distress over a possible threat to a person's physical or mental well-being.

Behavioral—Means related to the way a person acts.

Psychological—Refers to mental processes, including thoughts, feelings, and emotions.

Psychologist—A mental health professional who can do psychological testing and provide mental health counseling.

child). These factors complicate the grieving process due to the unexpected, sometimes violent nature of the loss, that feels inconsistent with expectations and desires for loved ones. In these cases, an initial adverse effect may be seen from participation in treatment, due to the increased focus on the loss. This reaction improves over time, as adjustment is facilitated. Two other factors impacting individual adjustment include the type of relationship the individual had with the deceased, and the resiliency of the individual.

Group therapy

Definition

Group therapy is a form of psychosocial treatment where a small group of patients meet regularly to talk, interact, and discuss problems with each other and the group leader (therapist).

Purpose

Group therapy attempts to give individuals a safe and comfortable place where they can work out problems and emotional issues. Patients gain insight into their own thoughts and behavior, and offer suggestions and support to others. In addition, patients who have a difficult time with interpersonal relationships can benefit from the social interactions that are a basic part of the group therapy experience.

Precautions

Patients who are suicidal, homicidal, psychotic, or in the midst of a major acute crisis are typically not referred for group therapy until their behavior and emotional state have stabilized. Depending on their level of functioning, cognitively impaired patients (like patients with organic brain disease or a **traumatic brain injury**) may also be unsuitable for group therapy intervention. Some patients with sociopathic traits are not suitable for most groups.

WWW.BOOKBAZ.IR

Description

A psychologist, psychiatrist, social worker, or other healthcare professional typically arranges and conducts group therapy sessions. In some therapy groups, two co-therapists share the responsibility of group leadership. Patients are selected on the basis of what they might gain from group therapy interaction and what they can contribute to the group as a whole.

Therapy groups may be homogeneous or heterogeneous. Homogeneous groups have members with similar diagnostic backgrounds (for example, they may all suffer from depression). Heterogeneous groups have a mix of individuals with different emotional issues. The number of group members varies widely, but is typically no more than 12. Groups may be time limited (with a predetermined number of sessions) or indefinite (where the group determines when therapy ends). Membership may be closed or open to new members once sessions begin.

The number of sessions in group therapy depends on the makeup, goals, and setting of the group. For example, a therapy group that is part of a substance abuse program to rehabilitate inpatients would be called short-term group therapy. This term is used because, as patients, the group members will only be in the hospital for a relatively short period of time. Long-term therapy groups may meet for six months, a year, or longer. The therapeutic approach used in therapy depends on the focus of the group and the psychological training of the therapist. Some common techniques include psychodynamic, cognitive-behavioral, and **Gestalt therapy**.

In a group therapy session, group members are encouraged to openly and honestly discuss the issues that brought them to therapy. They try to help other group members by offering their own suggestions, insights, and empathy regarding their problems. There are no definite rules for group therapy, only that members participate to the best of their ability. However, most therapy groups do have some basic ground rules that are usually discussed during the first session. Patients are asked not to share what goes on in therapy sessions with anyone outside of the group. This protects the confidentiality of the other members. They may also be asked not to see other group members socially outside of therapy because of the harmful effect it might have on the dynamics of the group.

The therapist's main task is to guide the group in self-discovery. Depending on the goals of the group and the training and style of the therapist, he or she may lead the group interaction or allow the group to take their own direction. Typically, the group leader does some of both, providing direction when the group gets off track while letting them set their own agenda. The therapist may guide the group by simply reinforcing the positive behaviors they engage in. For example, if a group member shows empathy to another member, or offers a constructive suggestion, the therapist will point this out and explain the value of these actions to the group. In almost all group therapy situations, the therapist will attempt to emphasize the common traits among group members so that members can gain a sense of group identity. Group members realize that others share the same issues they do.

The main benefit group therapy may have over individual **psychotherapy** is that some patients behave and react more like themselves in a group setting than they would one-on-one with a therapist. The group therapy patient gains a certain sense of identity and social acceptance from their membership in the group. Suddenly, they are not alone. They are surrounded by others who have the same anxieties and emotional issues that they have. Seeing how others deal with these issues may give them new solutions to their problems. Feedback from group members also offers them a unique insight into their own behavior, and the group provides a safe forum in which to practice new behaviors. Lastly, by helping others in the group work through their problems, group therapy members can gain more self-esteem. Group therapy may also simulate family experiences of patients and will allow family dynamic issues to emerge.

Self-help groups like Alcoholics Anonymous and Weight Watchers fall outside of the psychotherapy realm. These self-help groups do offer many of the same benefits of social support, identity, and belonging that make group therapy effective for many. Self-help group members meet to discuss a common area of concern (like **alcoholism**, **eating disorders**, **bereavement**, parenting). Group sessions are not run by a therapist, but by a nonprofessional leader, group member, or the group as a whole. Self-help groups are sometimes used in addition to psychotherapy or regular group therapy.

Preparation

Patients are typically referred for group therapy by a psychologist or psychiatrist. Some patients may need individual therapy first. Before group sessions begin, the therapist leading the session may conduct a short intake interview with the patient to determine if the group is right for the patient. This interview will also allow the therapist to determine if the addition of the patient will benefit the group. The patient may be

KEY TERMS

Cognitive-behavioral—A therapy technique that focuses on changing beliefs, images, and thoughts in order to change maladjusted behaviors.

Gestalt—A humanistic therapy technique that focuses on gaining an awareness of emotions and behaviors in the present rather than in the past.

Psychodynamic—A therapy technique that assumes improper or unwanted behavior is caused by unconscious, internal conflicts and focuses on gaining insight into these motivations.

given some preliminary information on the group before sessions begin. This may include guidelines for success (like being open, listening to others, taking risks), rules of the group (like maintaining confidentiality), and educational information on what group therapy is about.

Aftercare

The end of long-term group therapy may cause feelings of grief, loss, abandonment, anger, or rejection in some members. The group therapist will attempt to foster a sense of closure by encouraging members to explore their feelings and use newly acquired coping techniques to deal with them. Working through this termination phase of group therapy is an important part of the treatment process.

Results

Studies have shown that both group and individual psychotherapy benefit about 85% of the patients that participate in them. Optimally, patients gain a better understanding of themselves, and perhaps a stronger set of interpersonal and coping skills through the group therapy process. Some patients may continue therapy after group therapy ends, either individually or in another group setting.

Risks

Some very fragile patients may not be able to tolerate aggressive or hostile comments from group members. Patients who have trouble communicating in group situations may be at risk for dropping out of group therapy. If no one comments on their silence or makes an attempt to interact with them, they may begin to feel even more isolated and alone instead of identifying with the group. Therefore, the therapist usually attempts to encourage silent members to participate early on in treatment.

Growth hormone suppression test
see **Growth hormone tests**

Growth hormone tests

Definition

Growth hormone (hGH), or somatotropin, is a hormone responsible for normal body growth and development by stimulating protein production in muscle cells and energy release from the breakdown of fats. Tests for growth hormone include Somatotropin hormone test, Somatomedin C, Growth hormone suppression test (glucose loading test), and Growth hormone stimulation test (Arginine test or Insulin tolerance test).

Purpose

Growth hormone tests are ordered for the following reasons:

- to identify growth deficiencies, including delayed puberty and small stature in adolescents that result from pituitary or thyroid malfunction
- to aid in the diagnosis of hyperpituitarism that is evident in gigantism or acromegaly
- to screen for inadequate or reduced pituitary gland function

WWW.BOOKBAZ.IR

- to assist in the diagnosis of pituitary tumors or tumors related to the hypothalamus, an area of the brain
- to evaluate hGH therapy

Precautions

Taking certain drugs such as amphetamines, dopamine, **corticosteroids**, and phenothiazines may increase and decrease growth hormone secretion, respectively. Other factors influencing hGH secretion include **stress**, **exercise**, diet, and abnormal glucose levels. These tests should not be done within a week of any radioactive scan.

Description

Several hormones play important roles in human growth. The major human growth hormone (hGH), or somatotropin, is a protein made up of 191 amino acids that is secreted by the anterior pituitary gland and coordinates normal growth and development. Human growth is characterized by two spurts, one at birth and the other at **puberty**. hGH plays an important role at both of these times. Normal individuals have measurable levels of hGH throughout life. Yet levels of hGH fluctuate during the day and are affected by eating and exercise. Receptors that respond to hGH exist on cells and tissues throughout the body. The most obvious effect of hGH is on linear skeletal development. But the metabolic effects of hGH on muscle, the liver, and fat cells are critical to its function. Surprisingly, a 2004 study reported that obese people have lower-than-normal levels of human growth hormone in their bodies. Humans have two forms of hGH, and the functional difference between the two is unclear. They are both formed from the same gene, but one lacks the amino acids in positions 32–46.

GH is produced in the anterior portion of the pituitary gland by somatotrophs under the control of hormonal signals in the hypothalamus. Two hypothalamic hormones regulate hGH; they are growth hormone-releasing hormone (GHRH) and growth hormone—inhibiting hormone (GHIH). When blood glucose levels fall, GHRH triggers the secretion of stored hGH. As blood glucose levels rise, GHRH release is turned off. Increases in blood protein levels trigger a similar response. As a result of this hypothalamic feedback loop, hGH levels fluctuate throughout the day. Normal plasma hGH levels average 1–3 ng/ML with peaks as high as 60 ng/ML. In addition, plasma glucose and amino acid availability for growth is also regulated by the hormones adrenaline, glucagon, and insulin.

Most hGH is released at night. Peak spikes of hGH release occur around 10 p.m., midnight, and 2 a.m. The logic behind this night-time release is that most of hGH's effects are controlled by other hormones, including the somatomedins, IGH-I and IGH-II. As a result, the effects of hGH are spread out more evenly during the day.

A number of hormonal conditions can lead to excessive or diminished growth. Because of its critical role in producing hGH and other hormones, an abnormal pituitary gland will often yield altered growth. Dwarfism (very small stature) can be due to underproduction of hGH, lack of IGH-I, or a flaw in target tissue response to either of these growth hormones. Overproduction of hGH or IGH-I, or an exaggerated response to these hormones can lead to **gigantism** or **acromegaly**, both of which are characterized by a very large stature.

Gigantism is the result of hGH overproduction in early childhood leading to a skeletal height up to 8 feet (2.5 m) or more. Acromegaly results when hGH is overproduced after the onset of puberty. In this condition, the epiphyseal plates of the long bone of the body do not close, and they remain responsive to additional stimulated growth by hGH. This disorder is characterized by an enlarged skull, hands and feet, nose, neck, and tongue.

Somatotropin

Somatotropin is used to identify hGH deficiency in adolescents with short stature, delayed sexual maturity, and other growth deficiencies. It also aids in documenting excess hGH production that is responsible for gigantism or acromegaly, and confirms underactivity or overproduction of the pituitary gland (**hypopituitarism** or hyperpituitarism). However, due to the episodic secretion of hGH, as well as hGH production in response to stress, exercise, or other factors, random assays are not an adequate determination of hGH deficiency. To negate these variables and obtain more accurate readings, a blood sample can be drawn one to 1.5 hours after sleep (hGH levels increase during sleep), or strenuous exercise can be performed for 30 minutes before blood is drawn (hGH levels increase after exercise). The hGH levels at the end of an exercise period are expected to be maximal.

Somatomedin C

The somatomedin C test is usually ordered to detect pituitary abnormalities, hGH deficiency, and acromegaly. Also called insulin-like growth factor (IGF-1), somatomedin C is considered a more accurate

reflection of the blood concentration of hGH because such variables as time of day, activity levels, or diet do not influence the results. Somatomedin C is part of a group of peptides, called somatomedins, through which hGH exerts its effects. Because it circulates in the bloodstream bound to long-lasting proteins, it is more stable than hGH. Levels of somatomedin C depend on hGH levels, however. As a result, somatomedin C levels are low when hGH levels are deficient. Abnormally low test results of somatomedin C require an abnormally reduced or absent hGH during an hGH stimulation test in order to diagnose hGH deficiency. Nonpituitary causes of reduced somatomedin C include **malnutrition**, severe chronic illness, severe **liver disease**, **hypothyroidism**, and Laron's dwarfism.

Growth hormone stimulation test

The hGH stimulation test, also called hGH Provocation test, Insulin Tolerance, or Arginine test, is performed to test the body's ability to produce human growth hormone, and to identify suspected hGH deficiency. A normal patient can have low hGH levels, but if hGH is still low after stimulation, a diagnosis can be more accurately made.

Insulin-induced **hypoglycemia** (via intravenous injection of insulin) stimulates hGH and corticotropin secretion as well. If such stimulation is unsuccessful, then there is a malfunction of the anterior pituitary gland. Blood samples may be obtained following an energetic exercise session lasting 20 minutes.

A substance called hGH-releasing factor has recently been used for hGH stimulation. This approach promises to be more accurate and specific for hGH deficiency caused by the pituitary. Growth hormone deficiency is also suspected when x-ray determination of bone age indicates retarded growth in comparison to chronologic age. At present, the best method to identify hGH-deficient patients is a positive stimulation test followed by a positive response to a therapeutic trial of hGH.

Growth hormone suppression test

Also called the glucose loading test, this procedure is used to evaluate excessive baseline levels of human growth hormone, and to confirm diagnosis of gigantism in children and acromegaly in adults. The procedure requires two different blood samples, one drawn before the administration of 100 g of glucose (by mouth), and a second sample two hours after glucose ingestion.

Normally, a glucose load suppresses hGH secretion. In a patient with excessive hGH levels, failure of suppression indicates anterior pituitary dysfunction and confirms a diagnosis of **acromegaly and gigantism**.

Preparation

Somatotropin: This test requires a blood sample. The patient should be **fasting** (nothing to eat or drink from midnight the night before the test). Stress and/or exercise increases hGH levels, so the patient should be at complete rest for 30 minutes before the blood sample is drawn. If the physician has requested two samples, they should be drawn on consecutive days at approximately the same time on both days, preferably between 6 a.m. and 8 a.m.

Somatomedin C: This test requires a blood sample. The patient should have nothing to eat or drink from midnight the night before the test.

Growth hormone stimulation: This test requires intravenous administration of medications and the withdrawal of frequent blood samples, which are obtained at 0, 60, and 90 minutes after injection of arginine and/or insulin. The patient should have nothing to eat or drink after midnight the night before the test.

Growth hormone suppression: This test requires two blood samples, one before the test and another two hours after administration of 100 g of glucose solution by mouth. The patient should have nothing to eat or drink after midnight, and physical activity should be limited for 10–12 hours before the test.

Results

Normal results may vary from laboratory to laboratory but are usually within the following ranges:

Somatotropin:

- men: 5 ng/mL
- women: less than 10 ng/mL
- children: 0–10 ng/mL
- newborn: 10–40 ng/mL

Somatomedin C:

- adult: 42–110 ng/mL
- Child:
- 0–8 years: Girls 7–110 ng/ml; Boys 4–87 ng/mL
- 9–10 years: Girls 39–186 ng/ml; Boys 26–98 ng/mL
- 11–13 years: Girls 66–215 ng/ml; Boys 44–207 ng/mL
- 14–16 years: Girls 96–256 ng/ml; Boys 48 255 ng/mL

Growth hormone stimulation: greater than 10 ng/mL.

Growth hormone suppression: Normally, glucose suppresses hGH to levels of undetectable to 3 ng/mL in 30 minutes to two hours. In children, rebound stimulation may occur after two to five hours.

WWW.BOOKBAZ.IR

KEY TERMS

Acromegaly—A rare disease resulting from excessive growth hormone caused by a benign tumor. If such a tumor develops within the first 10 years of life, the result is gigantism (in which growth is accelerated) and not acromegaly. Symptoms include coarsening of the facial features, enlargement of the hands, feet, ears, and nose, jutting of the jaw, and a long face.

Dwarfism, pituitary—Short stature. When caused by inadequate amounts of growth hormone (as opposed to late growth spurt or genetics), hGH deficiency results in abnormally slow growth and short stature with normal proportions.

Gigantism—Excessive growth, especially in height, resulting from overproduction during childhood or adolescence of growth hormone by a pituitary tumor. Untreated, the tumor eventually destroys the pituitary gland, resulting in death during early adulthood. If the tumor develops after growth has stopped, the result is acromegaly, not gigantism.

Pituitary gland—The pituitary is the most important of the endocrine glands (glands that release hormones directly into the bloodstream). Sometimes referred to as the "master gland," the pituitary regulates and controls the activities of other endocrine glands and many body processes.

Risks

Growth hormone stimulation: Only minor discomfort is associated with this test, and results from the insertion of the IV line and the low blood sugar (hypoglycemia) induced by the insulin injection. Some patients may experience sleepiness, sweating and/or nervousness, all of which can be corrected after the test by ingestion of cookies, juice, or a glucose infusion. Severe cases of hypoglycemia may cause ketosis (excessive amounts of fatty acid by-products in the body), acidosis (a disturbance of the body's acid-base balance), or **shock**. With the close observation required for the test, these are unlikely.

Growth hormone suppression: Some patients experience nausea after the administration of this amount of glucose. Ice chips can alleviate this symptom.

Abnormal

Somatotropin hormone: Excess hGH is responsible for the syndromes of gigantism and acromegaly. Excess secretion is stimulated by **anorexia nervosa**, stress, hypoglycemia, and exercise. Decreased levels are seen in hGH deficiency, dwarfism, hyperglycemia, **failure to thrive**, and delayed sexual maturity.

Somatomedin C: Increased levels contribute to the syndromes of gigantism and acromegaly. Stress, major surgery, hypoglycemia, **starvation**, and exercise stimulate hGH secretion, which in turn stimulates somatomedin C.

Growth hormone stimulation: Decreased levels are seen in pituitary deficiency and hGH deficiency. Diseases of the pituitary can result in failure of the pituitary to secrete hGH and/or all the pituitary hormones. As a result, the hGH stimulation test will fail to stimulate hGH secretion.

Growth hormone suppression: The acromegaly syndrome elevates base hGH levels to 75 ng/mL, which in turn are not suppressed to less than 5 ng/mL during the test. Excess hGH secretion may cause unchanged or rising hGH levels in response to glucose loading, confirming a diagnosis of acromegaly or gigantism. In such cases, verification of results is required by repeating the test after a one-day rest.

Guided imagery

Definition

Guided imagery is the use of relaxation and mental visualization to improve mood and/or physical well-being.

Description

Guided imagery is simply the use of one's imagination to promote mental and physical health. It can be self-directed, where the individual puts himself into a relaxed state and creates his own images, or directed by others. When directed by others, an individual listens to a therapist, video, or audiotaped **exercise** that leads him through a relaxation and imagery exercise. Some therapists also use guided imagery in group settings.

Guided imagery is a two-part process. The first component involves reaching a state of deep relaxation through breathing and muscle relaxation techniques. During the relaxation phase, the person closes her eyes and focuses on the slow, in and out sensation of breathing. Or, she might focus on releasing the feelings of tension from her muscles, starting with the toes and working up to the top of the head. Relaxation tapes often feature soft music or tranquil, natural sounds such as rolling waves and chirping birds in order to promote feelings of relaxation.

Once complete relaxation is achieved, the second component of the exercise is the imagery, or visualization, itself. There are a number of different types of guided imagery techniques, limited only by the imagination. Some commonly used types include relaxation imagery, healing imagery, pain control imagery, and mental rehearsal.

Relaxation imagery

Relaxation imagery involves conjuring up pleasant, relaxing images that rest the mind and body. These may be experiences that have already happened, or new situations.

Healing imagery

Patients coping with diseases and injuries can imagine cancer cells dying, **wounds** healing, and the body mending itself. Or, patients may picture themselves healthy, happy, and symptom-free. Another healing imagery technique is based on the idea of *qi*, or energy flow, an idea borrowed from **traditional Chinese medicine**. Chinese medicine practitioners believe that illness is the result of a blockage or slowing of energy flow in the body. Individuals may use guided imagery to imagine energy moving freely throughout the body as a metaphor for good health.

Pain control imagery

Individuals can control pain through several imagery techniques. One method is to produce a mental image of the pain and then transform that image into something less frightening and more manageable. Another is to imagine the pain disappearing, and the patient as completely pain-free. Or, one may imagine the pain as something over which he has complete control. For example, patients with back problems may imagine their pain as a high voltage electric current surging through their spine. As they use guided imagery techniques, they can picture themselves reaching for an electrical switch and turning down the power on the current to alleviate the pain.

Mental rehearsal

Mental rehearsal involves imagining a situation or scenario and its ideal outcome. It can be used to reduce **anxiety** about an upcoming situation, such as labor and delivery, surgery, or even a critical life event such as an important competition or a job interview. Individuals picture themselves going through each step of the anxiety-producing event and then successfully completing it.

Purpose

The connection between the mind and physical health has been well documented and extensively studied. Positive mental imagery can promote relaxation and reduce **stress**, improve mood, control high blood pressure, alleviate **pain**, boost the immune system, and lower **cholesterol** and blood sugar levels. Through guided imagery techniques, patients can learn to control functions normally controlled by the autonomic nervous system, such as heart rate, blood pressure, respiratory rate, and body temperature.

One of the biggest benefits of using guided imagery as a therapeutic tool is its availability. Imagery can be used virtually anywhere, anytime. It is also an equal opportunity therapy. Although some initial training in the technique may be required, guided imagery is accessible to virtually everyone regardless of economic status, education, or geographical location.

Guided imagery also gives individuals a sense of empowerment, or control. The technique is induced by a therapist who guides the patient. The resulting mental imagery used is solely a product of the individual's imagination. Some individuals have difficulty imagining. They may not get actual clear images but perhaps vague feelings about the guided journey. However these individuals' brains and nervous systems responses seem to be the same as those with more detailed imaginings.

WWW.BOOKBAZ.IR

KEY TERMS

Aromatherapy—The therapeutic use of plant-derived, aromatic essential oils to promote physical and psychological well-being.

Autonomic nervous system—The part of the nervous system that controls so-called involuntary functions such as heart rate, salivary gland secretion, respiratory function, and pupil dilation.

Patients who feel uncomfortable "opening up" in a traditional therapist-patient session may feel more at ease with a self-directed therapy like guided imagery.

Preparation

For a successful guided imagery session, individuals should select a quiet, relaxing location where there is a comfortable place to sit or recline. If the guided imagery session is to be prompted with an audiotape or videotape, a stereo, VCR, or portable tape player should be available. Some people find that quiet background music improves their imagery sessions.

The session, which can last anywhere from a few minutes to an hour, should be uninterrupted. Taking the phone off the hook and asking family members for solitude can ensure a more successful and relaxing session.

Imagery combined with other relaxation techniques such as **yoga**, massage, or **aromatherapy** can greatly enhance the effects of these therapies. It can be done virtually anywhere.

Precautions

Because of the state of extreme relaxation involved in guided imagery, individuals should never attempt to use guided imagery while driving or operating heavy machinery.

Side effects

Guided imagery can induce sleepiness, and some individuals may fall asleep during a session. Other than this, there are no known adverse side effects to guided imagery.

Research and general acceptance

Use of guided imagery is a widely accepted practice among mental healthcare providers and is gaining acceptance as a powerful pain control tool across a number of medical disciplines. Results of a study conducted at The Cleveland Clinic Foundation and published in 1999 found that cardiac surgery patients who used a guided imagery tape prior to surgery experienced less pain and anxiety. These patients also left the hospital earlier following surgery than patients who used pain medication only.

Another study conducted by Harvard Medical School researchers found that for more than 200 patients undergoing invasive vascular or renal surgery, guided imagery controlled pain and anxiety more effectively than medication alone.

Paula Anne Ford-Martin

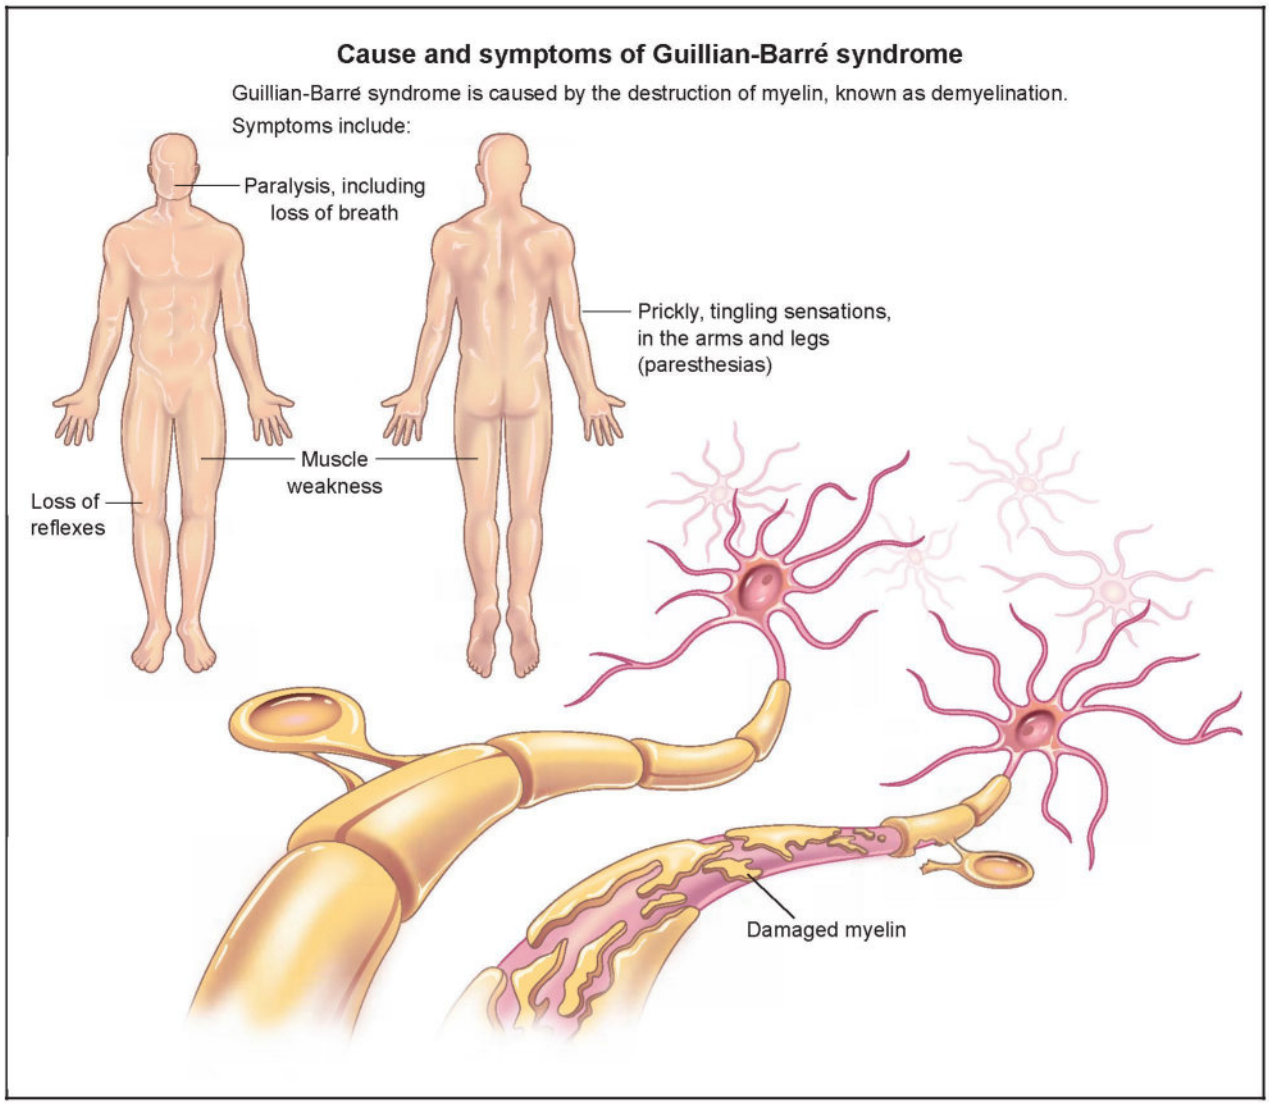
Guillain-Barré syndrome

Definition

Guillain-Barré syndrome (GBS), also called acute idiopathic polyneuritis, acute inflammatory polyneuropathy, infectious polyneuritis, and Landry-Guillain-Barré syndrome, causes progressive muscle weakness and **paralysis**, which develops over days or up to four weeks and lasts several weeks to several months.

Demographics

Guillain-Barré syndrome is found worldwide in all races. It is a rare disorder. In the United States, there are about three cases per 100,000 population. Risk increases with age, with infant at least risk, young adults accounting for about 1.5 cases per 100,000 population, and people over age 70 for 8.6 cases per 100,000 population.



(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

Description

Guillain-Barré syndrome is a disorder characterized by progressive symmetrical paralysis and loss of reflexes, usually beginning in the legs. The paralysis characteristically involves more than one limb, is progressive, and usually proceeds from the end of an extremity toward the torso. The classic scenario in GBS involves a patient who has just recovered from a typical, seemingly uncomplicated viral infection. Symptoms of muscle weakness appear one to four weeks later. The most common preceding infections are cytomegalovirus, herpes, **Epstein-Barr virus**, and viral hepatitis. A gastrointestinal infection with the bacteria *Campylobacter jejuni* is also common and may cause a severe type of GBS from which it is particularly difficult to recover. About 5% of GBS patients have a surgical procedure as a preceding event. GBS appears to be an autoimmune disorder, apparently caused by a misdirected immune response that results in the direct destruction of the myelin sheath surrounding the peripheral nerves or of the axon of the nerve itself.

Patients with lymphoma, **systemic lupus erythematosus**, or **AIDS** have a higher than normal risk of

WWW.BOOKBAZ.IR

GBS. Other GBS patients have recently received an immunization, while still others have no known preceding event. In 1976–77, there was a vastly increased number of GBS cases among people who had been recently vaccinated against the swine flu. The reason for this phenomenon has never been identified, and no other flu vaccine has caused such an increase in GBS cases.

Causes and symptoms

The cause of the weakness and paralysis of GBS is the loss of myelin, which is the material that coats nerve cells. (The loss of myelin is called demyelination.) Myelin is an insulating substance that is wrapped around all nerves in the body. Its function is to speed conduction of nerve impulses. Without myelin, nerve conduction slows or stops. GBS has a short, severe course. It causes inflammation and destruction of the myelin sheath, and it disturbs multiple nerves. Therefore, it is considered an acute inflammatory demyelinating polyneuropathy.

The reason for the destruction of myelin in GBS is not completely understood, although it is thought that the underlying problem is autoimmune in nature and is triggered in most cases by infection. An autoimmune disorder is one in which the body's immune system, trained to fight against such foreign invaders as viruses and bacteria, somehow becomes improperly programmed. The immune system becomes confused and is not able to distinguish between foreign invaders and the body itself. Elements of the immune system are unleashed against areas of the body, resulting in damage and destruction. For some reason, in the case of GBS, the myelin sheath appears to become a target for the body's own immune system.

The first symptoms of GBS consist of muscle weakness (legs first, then arms, then face), accompanied by prickly, tingling sensations (paresthesias). Symptoms affect both sides of the body simultaneously, a characteristic that helps distinguish GBS from other causes of weakness and paresthesias. Normal reflexes are first diminished, then lost. The weakness eventually affects all the voluntary muscles, resulting in paralysis. When those muscles necessary for breathing become paralyzed, the patient must be placed on a mechanical ventilator, which takes over the function of breathing. This occurs about 30% of the time. Very severely ill GBS patients may have complications stemming from other nervous system abnormalities that can result in problems with fluid balance in the body, severely fluctuating blood pressure, and heart rhythm irregularities.

Diagnosis

Diagnosis of GBS is made by looking for a particular cluster of symptoms (progressively worse muscle weakness and then paralysis), and by analyzing the cerebrospinal fluid (CSF) that bathes the brain and spinal canal. This fluid is obtained by a **lumbar puncture**, which consists of inserting a needle into the lower back (lumbar region) and withdrawing a small amount of CSF. When examined in a laboratory, the CSF of a person with GBS will reveal a greater-than-normal quantity of protein, normal numbers of white blood cells, and a normal amount of sugar. Electrodiagnostic studies may show slowing or block of conduction in nerve endings in parts of the body other than the brain. Minor abnormalities will be present in 90% of patients.

Treatment

There is no direct treatment for GBS. Instead, treatments are used that support the patient with the disabilities caused by the disease. The progress of paralysis must be carefully monitored, in order to provide mechanical assistance for breathing if it becomes necessary. Careful attention must also be paid to the amount of fluid the patient is taking in by drinking and eliminating by urinating. Blood pressure, heart rate, and heart rhythm also must be monitored.

A procedure called **plasmapheresis**, performed early in the course of GBS, has been shown to shorten the course and severity of GBS. Plasmapheresis consists of withdrawing the patient's blood, passing it through an instrument that separates the different types of blood cells, and returning all the cellular components (red and white blood cells and platelets) along with either donor plasma or a manufactured replacement solution. This is thought to rid the blood of the substances that are attacking the patient's myelin.

It has also been shown that the use of high doses of immunoglobulin given intravenously (by drip through a needle in a vein) may be just as helpful as plasmapheresis. Immunoglobulin is a substance naturally manufactured by the body's immune system in response to various threats. It is interesting to note that corticosteroid drugs (such as prednisone), often the mainstay of anti-autoimmune disease treatment, are not only unhelpful, but may in fact be harmful to patients with GBS.

Physical therapy and **occupational therapy** may be used to help restore function as the patient begins to recover.

KEY TERMS

Autoimmune disorder—A disorder in which the body's immune system produces antibodies that attack its own healthy tissues or blood components.

Demyelination—Disruption or destruction of the myelin sheath, leaving a bare nerve. Results in a slowing or stopping of impulses traveling along that nerve.

Idiopathic—Of unknown origin; without a known cause.

Inflammation—The body's response to tissue damage. Includes warmth, swelling, redness, and pain in the affected part.

Myelin—The substance that is wrapped around nerves. Myelin is responsible for speed and efficiency of impulses traveling through those nerves. When the myelin sheath is damaged, nerve communication is disrupted.

Peripheral nervous system—Nerves that are not part of the brain of spinal cord.

Systemic lupus erythematosus (SLE)—A chronic, inflammatory, autoimmune disorder in which the individual's immune system attacks, injures, and destroys the body's own organs and tissues. It may affect many organ systems including the skin, joints, lungs, heart, and kidneys.

Prognosis

About 85% of GBS patients make reasonably good recoveries. However, 30% of adult patients, and a greater percentage of children, never fully regain their previous level of muscle strength. Some of these patients suffer from residual weakness, others from permanent paralysis. About 10% of GBS patients begin to improve, then experience a relapse; these patients suffer chronic GBS symptoms. Between 2% and 12% of all GBS patients die from complications of the disorder, with patients over age 60 most at risk for death. Cause of death most often is either from cardiac rhythm disturbances or from ventilator-related complications such as **pneumonia**.

Patients with certain characteristics tend to have a worse outcome. These include people of older age, those who required breathing support with a mechanical ventilator, and those who had their worst symptoms within the first seven days.

Prevention

Because so little is known about what causes GBS to develop, there are no known methods of prevention.

Guinea worm infection

Definition

Infection occurs when the parasitic guinea worm resides within the body. Infection is not apparent until a pregnant female worm prepares to expel embryos. The infection is rarely fatal, but the latter stage is painful. The infection is also referred to as dracunculiasis, and less commonly as dracontiasis.

WWW.BOOKBAZ.IR

Description

Before the early 1980s, guinea worms infected 10–15 million people annually in central Africa and parts of Asia. By 1996, worldwide incidence of infection fell to fewer than 153,000 cases per year. Complete eradication of guinea worm infection is a goal of international water safety programs.

To survive, guinea worms require three things: water during the embryo stage, an intermediate host during early maturation, and a human host during adulthood. In bodies of water, such as ponds, guinea worm embryos are eaten by tiny, lobster-like water fleas. Once ingested, the embryos mature into larvae.

Humans become hosts by consuming water containing infected water fleas. Once in the human intestine, larvae burrow into surrounding tissue. After three to four, the worms mate. Males die soon after, but pregnant females continue to grow. As adults, each threadlike worm can be three feet long and harbor three million embryos. More than one guinea worm can infect a person at the same time.

About eight months later, the female prepares to expel mature embryos by migrating toward the skin surface. Until this point, most people are unaware that they are infected. Extreme **pain** occurs as the worm emerges from under the skin, often around the infected person's ankle. The pain is temporarily relieved by immersing the area in water, an act that contaminates the water and starts the cycle again.

KEY TERMS

Guinea worm embryo—The guinea worm at its earliest life stage prior to or shortly after being expelled from an adult female worm.

Guinea worm larvae—The guinea worm during its middle life stage as it matures within a water flea. The larvae can only grow to adulthood within a human host.

Host—With regard to guinea worm infection, either the water flea or human from which the worm gets nourishment and shelter as it matures.

Secondary infection—An illness—typically caused by bacteria—that follows from a guinea worm infection.

Causes and symptoms

Dracunculus medinensis, or guinea worm, causes infection. Symptoms are commonly absent until a pregnant worm prepares to expel embryos. By secreting an irritating chemical, the worm causes a blister to form on the skin surface. This chemical also causes nausea, **vomiting**, **dizziness**, and **diarrhea**. The blister is accompanied by a burning, stabbing pain and can form anywhere on the body; but, the usual site is the lower leg or foot. Once the blister breaks, an open sore remains until the worm has expelled all the embryos.

Diagnosis

Guinea worm infection is identified by the symptoms.

Treatment

Most people infected with guinea worm rely on traditional medicine. The worm is extracted by gently and gradually pulling the worm out and winding it around a small strip of wood. Surgical removal is possible, but rarely done in rural areas. Extraction is complemented by herbs and oils to treat the wound site. Such treatment can ease extraction and may help prevent secondary infections.

Modern medicine offers safe surgical removal of the guinea worm, and drug therapy can prevent infection and pain. Using drugs to combat the worms has had mixed results.

Prognosis

If the worm is completely removed, the wound heals in approximately two to four weeks. However, if a worm emerges from a sensitive area, such as the sole of a foot, or if several worms are involved, healing requires more time. Recovery is also complicated if the worm breaks during extraction. Serious secondary infections frequently occur in such situations. There is the risk of permanent disability in some cases, and having one guinea worm infection does not confer immunity against future infections.

Prevention

Guinea worm infection is prevented by disrupting transmission. Wells and other protected water sources are usually safe from being contaminated with worm embryos. In open water sources, poisons may be used to kill water fleas. Otherwise, water must be boiled or filtered.

Julia Barrett

Gulf War syndrome

Definition

Gulf War syndrome describes a wide spectrum of illnesses and symptoms ranging from **asthma** to **sexual dysfunction** that have been reported by United States and United States' allied soldiers who served in the Persian Gulf War in 1990–1991.

Description

Between 1994 and 1999, 145 federally funded research studies on Gulf War-related illnesses were undertaken at a cost of over $133 million. Despite this investment and the data collected from over 100,000 veterans who have registered with the Department of Defense (DOD) and/or Veterans Administration (VA) as having Gulf War-related illnesses, there is still much debate over the origin and nature of Gulf War syndrome. A 2006 study for the U.S. Department of Veterans Affairs concluded Gulf War Syndrome does not constitute a single illness and the DOD has failed to establish a definite cause for the disorder. Veterans who have the illness experience a wide range of debilitating symptoms that elude a single diagnosis. Common symptoms include **fatigue**, trouble breathing, headaches, disturbed sleep, **memory loss**, and lack of concentration. Similar experiences among Gulf War veterans have been reported in the United Kingdom and Canada.

Causes and symptoms

There is much current debate over a possible causative agent for Gulf War syndrome other than the **stress** of warfare. Intensive efforts by the Veterans Administration and other public and private institutions have investigated a wide range of potential factors. These include chemical and biological weapons, the immunizations and preventive treatments used to protect against them, smoke from oil well fires, exposure to depleted uranium, and diseases endemic to the Arabian peninsula. So far investigators have not approached a consensus. In its final report released in December 2000, the Presidential Special Oversight Board for Department of Defense Investigations of Gulf War Chemical and Biological Incidents cited combat stress as a possible causative factor, but called for further research. There is also a likelihood that U.S. and allied forces were exposed to low levels of sarin and/or cyclosarin (nerve gases) released during the destruction of Iraqi munitions at Kharnisiyah, Iraq, and that these chemicals might be linked to the syndrome. In July 1997, the VA informed approximately 100,000 U.S. servicemen of their possible exposure to the nerve agents.

In October 1999, the U.S. Pentagon released a report that hypothesized that an experimental drug known as pyriostigmine bromide (PB) might be linked to the physical symptoms manifested in Gulf War Syndrome. The experimental drug was given to U.S. and Canadian troops during the war to protect soldiers against the effects of the chemical nerve agent soman. It has also been suggested that botulinum toxoid and **anthrax** vaccinations administered to soldiers during the conflict may be responsible for some manifestations of the syndrome.

Some studies have shown that Gulf War veterans have a higher incidence of positive tests for *Mycoplasma fermentans*, a bacteria, in their bloodstream. However, other clinical studies have not found a link between the bacterial infection and Gulf War-related illnesses.

Statistical analysis tells us that the following symptoms are about twice as likely to appear in Gulf War veterans than in their non-combat peers: depression, posttraumatic stress disorder (PTSD), chronic fatigue, cognitive dysfunction (diminished ability to calculate, order thoughts, evaluate, learn, and remember), **bronchitis**, asthma, **fibromyalgia**, alcohol abuse, **anxiety**, and sexual discomfort. PTSD is the modern equivalent of shell shock (World War I) and battle fatigue (World War II). It encompasses most of the psychological symptoms of war veterans, including nightmares, panic at sudden loud noises, and inability to adjust to peacetime living. **Chronic fatigue syndrome** has a specific medical definition that attempts to separate common fatigue from a more disabling illness in hope of finding a specific cause. Fibromyalgia is another newly defined syndrome, and as such it has arbitrarily rigid defining characteristics. These include a certain duration of illness, a specified minimum number of joint and muscle **pain** located in designated areas of the body, sleep disturbances, and other associated symptoms and signs.

WWW.BOOKBAZ.IR

Researchers have identified three distinct syndromes and several variations in Gulf War veterans. Type one patients suffer primarily from impaired thinking. Type two patients have a greater degree of confusion and ataxia (loss of coordination). Type three patients were the most affected by joint pains, muscle pains, and extremity paresthesias (unnatural sensations like burning or tingling in the arms and legs). In each of the three types, researchers found different but measurable impairments on objective testing of neurological function. The business of the nervous system is much more complex and subtle than other body functions. Measuring it requires equally complex effort. The tests used in this study carefully measured and compared localized nerve performance at several different tasks against the same values in normal subjects. Brain wave response to noise and touch, eye muscle response to spinning, and caloric testing (stimulation of the ear with warm and cold water, which causes vertigo) were clearly different between the normal and the test subjects. The researchers concluded that there was "a generalized injury to the nervous system." Another research group concluded their study by stating that there was "a spectrum of neurologic injury involving the central, peripheral, and autonomic nervous systems."

Diagnosis

Until there is a clear definition of the disease, diagnosis is primarily an **exercise** in identifying those Gulf War veterans who have undefined illness in an effort to learn more about them and their symptoms. Both the Department of Defense and the Veterans Administration currently have programs devoted to this problem. Both the DOD's Comprehensive Clinical Evaluation Program and the VA's Persian Gulf Registry provide free, in-depth medical evaluations to Gulf War veterans and their families. In addition to providing individual veterans with critical medical care, these organizations use the cumulative data from these programs to advance research on Gulf War Syndrome itself.

Treatment

Specific treatment awaits specific diagnosis and identification of a causative agent. Meanwhile, veterans can benefit from the wide variety of supportive and non-specific approaches to this and similar problems. There are many drugs available for symptomatic relief. Psychological counseling by those specializing in this area can be immensely beneficial, even lifesaving for those contemplating **suicide**. Veterans' benefits are available for those who are impaired by their symptoms.

KEY TERMS

Ataxia—Lack of coordination.

Caloric testing—Flushing warm and cold water into the ear stimulates the labyrinth and causes vertigo and nystagmus if all the nerve pathways are intact.

Endemic—Always there.

Paresthesia—An altered sensation often described as burning, tingling, or pin pricks.

Syndrome—Common features of a disease or features that appear together often enough to suggest they may represent a single, as yet unknown, disease entity. When a syndrome is first identified, an attempt is made to define it as strictly as possible, even to the exclusion of some cases, in order to separate out a pure enough sample to study. This process is most likely to identify a cause, a positive method of diagnosis, and a treatment. Later on, less typical cases can be considered.

Alternatives

The symptoms can be worked with using many modalities of alternative health care. The key to working successfully with people living their lives with Gulf War syndrome is long-term, ongoing care, whether it be **hypnotherapy**, **acupuncture**, homeopathy, **nutrition**, vitamin/mineral therapy, or bodywork.

Experimental treatment with **antibiotics** is advocated by some healthcare professionals who believe that Gulf War illness is related to a *Mycoplasma fermentans* bacterial infection. However, a conclusive link has not been clinically proven.

Prognosis

The outlook for Persian Gulf War veterans is unclear, but will hopefully improve as more information is gathered about the illness. Gradual return to a functioning life may take many years of work and much help. It is important to note that even in the absence of an identifiable and curable cause, recovery is possible.

Gynecomastia

Definition

Gynecomastia is a benign (noncancerous) condition caused by the development of unusually large mammary glands in the male resulting in enlargement of the male breast. The English word comes from two Greek words meaning "woman" and "breast." Enlargement of the male breast caused solely by deposits of fat associated with **obesity** is called pseudogynecomastia or lipomastia.

Demographics

Gynecomastia by definition is a condition found only in males. It occurs in three different age groups: infants, adolescents, and older men. Between 60% and 90% of male infants have temporary gynecomastia resulting from exposure to the mother's high estrogen levels during **pregnancy**. Various studies report the rate of gynecomastia in male adolescents as being between four and 69%.

In older men, the rate of gynecomastia is between 24% and 65%. The condition is thought to be equally common in all races and ethnic groups.

Description

The enlargement of the male breast that characterizes gynecomastia is caused by the growth of glandular tissue directly under the areola (the pigmented skin surrounding the nipple), usually in a symmetrical fashion just below the nipple. In most cases the extra glandular tissue is less than two inches across. In older men there may be extra fibrous tissue accumulating below the areola along with the increased growth of glandular tissue. Mild gynecomastia may take the form of puffy nipples, while severe gynecomastia—particularly in older men—may take the form of large sagging breasts, often referred to informally as "man boobs." The enlarged lump of glandular tissue under the nipple typically feels rubbery in texture.

In most cases the swelling of the breast is bilateral (affects both breasts) but it may also be unilateral, occurring in only one breast. In some cases the gynecomastia affects both breasts but not to the same extent, so that one is noticeably larger than the other.

Doctors divide gynecomastia into two major categories: physiologic and pathologic. Physiologic gynecomastia is caused by an imbalance in the amounts of estrogen and androgen in the man's body in favor of estrogen. Although estrogen is usually thought of as a female sex hormone, men's bodies also produce small amounts of it. Normally, the male body produces much more testosterone, a male sex hormone, than estrogen; the usual ratio is 100:1. But if the testosterone level in the male body is low for some reason or the estrogen level unusually high, gynecomastia can occur. In male infants, the imbalance between estrogen and testosterone results from exposure to the estrogen in the mother's circulation before birth; gynecomastia in infants typically goes away between two and three weeks after birth. In adolescent boys, the imbalance between the two sex hormones leads to gynecomastia lasting anywhere from six months to two or three years. Gynecomastia in older males

WWW.BOOKBAZ.IR

typically results from a combination of causes: lowered levels of testosterone secretion; the conversion of some of the testosterone that is produced to estradiol, a female sex hormone; and the side effects of certain drugs that are frequently prescribed for older men.

Pathologic gynecomastia differs from physiologic gynecomastia in that it is associated with other diseases and disorders. These may include diseases that result in lowered testosterone production or increased estrogen production. Disorders associated with **low testosterone** production include genetic disorders like **Klinefelter syndrome** and Kallmann syndrome; **trauma** to or viral infection of the testicles; tumors of the pituitary gland; **hyperthyroidism**; kidney failure; **malnutrition**; or **small cell lung cancer**, gastric carcinoma, renal cell carcinoma, or kidney failure. Disorders associated with increased production of estrogen or increased conversion of testosterone to estradiol include cancers of the lung, kidney, and digestive tract; and chronic **liver disease**, malnutrition, hyperthyroidism, and tumors of the adrenal glands.

Risk factors

Risk factors for gynecomastia include:

- Age. Infants, boys undergoing puberty, and men over 50 are at increased risk of gynecomastia.
- Family history of gynecomastia.
- Use of anabolic steroids or injected androgens to improve athletic performance.
- Diagnosis with Klinefelter syndrome, Kallmann syndrome, or other genetic disorders that affect the size of the testes or their ability to produce testosterone.
- Kidney disease, liver disease, or thyroid disease.
- Cancers that are hormonally active, including cancers of the kidneys, digestive tract, and lungs.
- Having to take prescription drugs that stimulate estrogen synthesis, lower testosterone production, or are otherwise known to cause gynecomastia as a side effect.

Causes and symptoms

Causes

As has been noted, gynecomastia can be caused by a number of conditions, ranging from normal shifts in hormone balance at certain points in the male life cycle to genetic conditions, medication side effects, and cancer. The causes for which males seek help with gynecomastia are as follows in order of frequency:

- Persistent (two years or longer) gynecomastia of puberty: 25%
- Drug–related gynecomastia: 10% to 25%
- Idiopathic (no detectable disease or disorder): 25%
- Cirrhosis of the liver or malnutrition: 8%
- Underdeveloped testicles: 8%
- Testicular tumors: 3%
- Hyperthyroidism: 1.5%
- Kidney disease: 1%

Symptoms

The symptoms of gynecomastia are visible enlargement of the breast. Most boys and men will also feel some **pain** or tenderness around the areola. A discharge from the nipple is not normal with gynecomastia, however, and may indicate **breast cancer**, as one percent of all cancers of the breast occur in males.

Diagnosis

A formal diagnosis is not usually necessary for male infants as the condition is temporary in infancy and does not require treatment.

In adolescent boys and older men, diagnosis is based on a combination of patient and family history, an office examination, imaging studies, and a blood test. In terms of patient history, the doctor will ask the patient's age at the time the gynecomastia first appeared, how long it has been present, whether the patient is using **steroids**, whether the patient is consuming alcohol or drugs of abuse, what prescription medications the patient is taking, and whether there is a family history of gynecomastia.

Examination

The office examination is intended to check for abnormally small testicles, testicular tumors, and other abnormalities of the male genitals, and to distinguish between gynecomastia and pseudogynecomastia. To tell whether the breast is enlarged by glandular tissue or only by fat, the doctor will ask the patient to lie flat on the examination table with arms raised above the head. The doctor will then place his or her thumbs on either side of the nipple and slowly bring the thumbs together. If the patient has gynecomastia, the doctor will feel a ridge of glandular tissue. If only fat is present, no such ridge will be felt.

The doctor will also check to see whether there is any discharge from the patient's nipple, and for signs of thyroid, kidney, or liver disease.

Tests

The tests most commonly performed are a mammogram and a blood test to check for abnormalities in

KEY TERMS

Areola—The area of pigmented skin surrounding the human nipple in both males and females. It is roughly circular in shape.

Bilateral—Located on or affecting both sides of the body.

Hyperthyroidism—A condition in which the thyroid gland in the throat is overactive and produces too much thyroid hormone.

Idiopathic—Of unknown cause or spontaneous origin.

Kallmann syndrome—A rare genetic disorder in which the hypothalamus does not produce enough gonadotropin–releasing hormone, leading to underfunctioning of the testes in males and the ovaries in females.

Klinefelter syndrome—A genetic disorder in which a male has an extra X chromosome, making his genetic sex classification 47, XXY. About a third of males with Klinefelter syndrome develop gynecomastia.

Liposuction—A cosmetic surgery technique for removing unwanted fat cells from the abdomen, hips, thighs, or male breast while doing as little damage as possible to nearby connective tissue and blood vessels.

Pseudogynecomastia—Enlargement of the male breast caused solely by fat accumulation. It is also called lipomastia.

Unilateral—Located on or affecting only one side of the body.

thyroid, liver, or kidney function. If the doctor suspects an underlying cancer, the patient may also be given an MRI, **ultrasound** of the testicles, a chest x ray, or a tissue biopsy.

Treatment

Treatment for gynecomastia ranges from none at all to drugs or surgery. Adolescents may also be referred to **psychotherapy** to help them cope with the social embarrassment caused by the disorder and their psychological reactions to it.

Gynecomastia by itself is not a danger to health, although its underlying cause may require treatment. In many cases, treatment of that cause relieves the gynecomastia as well. In the case of adolescents, most doctors recommend simple observation of the condition (a checkup every three to six months), as it usually goes away by itself in two to three years. If the adolescent is having significant pain in the enlarged breasts, if the condition persists beyond three years, or if the teenager is having serious psychological problems related to the gynecomastia, the doctor may recommend breast surgery. Surgical treatment may consist either of **mastectomy** (surgical removal of the glandular tissue in the breast) or **liposuction** (removal of the fat surrounding the glandular tissue while leaving the glandular tissue intact).

Pseudogynecomastia can be helped somewhat by encouraging the patient to lose weight; however, it is not possible to target a specific area of the body for fat loss, and the patient may still have larger breasts than he would like. Liposuction can also be used successfully to treat pseudogynecomastia.

Drugs

Some older men can be treated with tamoxifen or raloxifene, drugs used to treat breast cancer in women; between 70% and 80% report complete reduction of the gynecomastia after taking these drugs. In addition, men whose gynecomastia is caused by prescription medications for other conditions may be helped by having their doctor switch them to another drug. Drugs known to cause gynecomastia as a side effect include methyldopa, busulfan, tricyclic antidepressants, diazepam, penicillamine, omeprazole, phenothiazines, **calcium channel blockers**, angiotensin–converting enzyme (ACE) inhibitors, ketoconazole, metronidazole, alkylating agents, cisplatin, spironolactone, cimetidine, flutamide, **finasteride**, and etomidate.

Patients abusing alcohol, heroin, or **marijuana** may be helped by stopping their use of these substances, as all three are known to cause gynecomastia.

Prognosis

In 90% of cases, gynecomastia will eventually go away by itself. For those patients with persistent gynecomastia, drug therapy or **plastic surgery** will usually relieve the condition. Men with Klinefelter syndrome, however, have a 10–to 20–fold increased risk of breast

WWW.BOOKBAZ.IR

cancer, and should be checked for any abnormalities in their breasts during every routine office physical.

Prevention

There is no known way to prevent gynecomastia in male infants, whether physiologic or pathologic. Male adolescents can lower their risk of gynecomastia by avoiding steroids for muscle building, illicit drugs, and heavy alcohol consumption. Older men should ask their doctor whether any of the medications currently prescribed for them are known to cause gynecomastia, and if so, whether other drugs can be substituted.

H1N1 influenza A

Definition

Pandemic 2009 H1N1 **influenza**, initially termed a swine flu, is an infectious respiratory disease caused by a subtype of the influenza A virus first identified in April 2009. It is also denoted as the A (H1N1) virus. The virus and associated influenza spread rapidly around the world, and on June 11, 2009, World Health Organization (WHO) officials declared H1N1 influenza to be a global pandemic, the first new pandemic of the twenty-first century.

Demographics

Because the 2009 H1N1 influenza virus was a novel (not previously identified) virus, and because the virus and associated flu became subjects of intense research, information about the virus accumulated rapidly. As of July 2009, the World Health Organization (WHO) offices reported over 94,000 laboratory-confirmed cases of 2009 H1N1 influenza in 135 countries. At least 700 deaths had been attributed to the novel virus, and WHO officials characterized the 2009 H1N1 flu as the fastest spreading pandemic on record.

Despite high initial estimates, by June 24, 2009, Mexico had reported 7,847 confirmed cases and 115 laboratory-confirmed deaths; the United States reported 21,449 confirmed cases and 87 deaths, and Canada reported 6,457 cases and 15 deaths. Deaths were also reported in Columbia, Costa Rica, Dominican Republic, Guatemala, the Philippines, and the United Kingdom. The spread of the virus into the Southern Hemisphere was evidenced by Australia's reporting of 2,857 cases, including two deaths; Argentina's reporting of 1,213 cases, including seven deaths; and Chile's reporting 4,315 cases, including four deaths. As with all reports related to a developing outbreak, daily reports of cases and deaths were simply considered by experts to be a snapshot of data; both the number of countries reporting and cases confirmed were expected to increase until the pandemic subsided. In July 2009, with the pandemic well established in both the Northern and Southern Hemispheres, WHO officials stopped accumulating individual case counts in favor of concentrating on pandemic flu mitigation strategies such as vaccine and antiviral medication development and delivery. In developing countries with established outbreaks, data were difficult to collect and prone to error. Counting individual cases was also difficult because many were mild and went unreported.

Newswires were often filled with unverified reports and even the time difference between offices reporting laboratory-confirmed results could seemingly swing figures rapidly. In addition, there was often a delay or backlog in such reporting. Uncertainties in the number of cases and confirmed deaths created a degree of uncertainty in assessments of the lethality of the virus and course of the outbreak. As of August 2009, there was no evidence that the H1N1 pandemic would be more lethal on a case-by-case basis than a typical seasonal flu. However, pandemic flu viruses often cause significant global deaths because so many more people are infected than in normal influenza seasons.

Common seasonal influenza (the type for which vaccinations are offered each year) normally accounts for about 200,000 hospitalizations and 36,000 deaths annually in the United States. Globally, WHO officials estimate that between 300,000 and 500,000 people die from flu complications each year. Although people of all ages can contract influenza, young children and the elderly, along with those with compromised immune systems (e.g., cancer patients or those with HIV/AIDS) are most at risk during a normal seasonal flu. Most deaths are caused by **pneumonia**, a common complication of seasonal flu. During the initial outbreak of 2009 H1N1 flu in Mexico, reports indicated that otherwise healthy adults aged 20 to 44 years were dying of the disease in higher than expected

WWW.BOOKBAZ.IR

numbers. By the end of July 2009, in the United States, approximately 50% of the reported cases of pandemic H1N1 flu occurred in young people from five to 24 years of age, and the highest rate of hospitalization was among infants and young children under four years of age. Although there is no definitive cause, the pattern of illness differs from normal seasonal flu, which usually results in a greater number of cases in the elderly. A report published in the medical journal *The Lancet* showed that early in the pandemic, pregnant women were four times as likely as other people who contract swine flu to require hospitalization. The physiological reasons remain under study.

Description

In April 2009, scientists at the U.S. Centers for Disease Control and Prevention (CDC) and at a research laboratory in Winnipeg, Canada, confirmed that a new strain of influenza was causing illness in humans. Genetic analysis showed that although the H1N1 virus is a novel genetic reassortment of genes of swine, human, and avian origin, the majority of the H1N1 genome is traceable and comparable to other viruses that cause seasonal influenza.

It remained a subject of intense research as to when and where the 2009 H1N1 flu virus may have entered the human population. Although the first cases erupted in Mexico and the United States in March and April 2009, this did not mean that that the genetic reassortment of the virus took place in Mexico or the United States or that the virus entered the human population in either country.

The 2009 H1N1 influenza virus was initially classified as a swine flu because it contains swine flu genes. This means only that the virus passed through swine at some point in its evolution. When and where the virus passed through swine was a subject of continued investigation. Although probable, it was not a certainty that the virus was most recently transmitted from swine to humans. Based on preliminary genetic analysis, experts conjectured such a transfer might have taken place in late 2008. As of June 12, 2009, however, none of the cases encountered in the 2009 H1N1 flu outbreak could be definitively traced to contact with pigs. In fact, the first confirmed outbreak of H1N1 recorded in swine was on a Canadian farm. Experts strongly suspected that a human farm worker who had traveled from Mexico infected the swine.

H1N1 strains of influenza are common in pigs, and swine flu viruses can be transmitted from pigs to humans who are in close contact with infected animals. However, before the 2009 H1N1 outbreak, documented transmission of recent swine flu viruses from person to person was extremely limited and had not resulted in documented outbreaks of human disease.

What made health experts in 2009 so concerned about the new H1N1 virus was its being a novel virus of unknown lethality that had gained the ability to efficiently pass from person to person (human transmission). Because 2009 H1N1 flu was new, humans had no immunity to it. As a result, the resources of the WHO, the CDC, state **public health** departments, and various international organizations charged with protecting public health were mobilized to attempt to mitigate a worldwide influenza pandemic.

Understanding the influenza virus

Viruses are simple organisms consisting of a protein matrix containing genetic information. They are so small that they can be seen only with an electron microscope. Because they are metabolically inert outside a host cell, viruses cannot reproduce on their own. They are parasites and must enter a host cell and take over the host cell's resources in order to make millions of new virus particles.

Influenza is caused by a hardy group of viruses belonging to the Orthomyxoviridae family. There are three types of influenza viruses: types A, B, and C. Type A influenza virus is the most threatening to humans. The type B virus is stable, changing little from year to year, and can be effectively controlled through **vaccination**. Type C influenza viruses cause only mild illness in humans. The type A virus easily changes, or mutates, into new strains or subtypes. Each strain contains slightly different genetic information. Because of this difference, no single vaccine is completely effective against all type A viruses, and whenever a new strain arises, as in the case of the 2009 H1N1, the body's immune system treats the virus as a completely new antigen.

How new strains develop

Humans are not the only animals vulnerable to influenza A infections. Different strains of influenza A cause disease in other animals, including wild birds, chickens, ducks, and turkeys (collectively called avian or bird flu), in addition to pigs, horses, ferrets, whales, seals, and dogs. Pigs and birds are the critical species in the development of new flu strains that can infect humans. Wild birds serve as a reservoir for the influenza A viruses; some strain of **avian flu** is always present in the wild bird population. Birds shed live virus in their droppings (feces), and because many species of bird migrate long distances, they can infect

large areas. Pigs carry their own strains of influenza A, but they also can become infected with avian influenza if they are exposed to infected bird droppings or contaminated water. If a pig simultaneously becomes infected with a strain of swine influenza and a strain of avian influenza, when the virus reproduces, genetic information can be exchanged so that new strains of influenza A develop that incorporate some genetic material from the avian virus and some genetic material from the swine virus.

Most new strains of influenza that result from a recombination or reassortment of avian and swine flu viruses do not survive, cannot infect humans, or die out quickly. Occasionally, however, a strain develops that can infect humans and that has the ability to pass from pig to human and from person to person. Because the virus is new to humans, the body has few defenses against it, and the vaccines included in seasonal flu shots are ineffective against it. When a new strain of flu arises that can pass easily from person to person, it has the potential to cause a pandemic, rapidly infecting and sometimes killing millions of people across the world.

Influenza pandemics have occurred during thousands of years of recorded history. The worst influenza pandemic in modern history occurred in 1918–1919 and killed an estimated 20–40 million people. In 1957, another pandemic known as the asian flu killed about 70,000 Americans. This was followed by the pandemic Hong Kong flu in 1968. Then in 1976, Americans experienced a swine flu scare. During February 1976, several recruits at the Army Fort Dix in New Jersey developed unusually severe flu symptoms. When samples from some of the sick men were sent to the CDC for analysis, four samples showed a previously unknown flu virus that appeared to be similar to the virus that caused the 1918–1919 pandemic. After one soldier died of flu, the United States began a $135 million emergency immunization program. However, the 1976 virus proved to be much less dangerous than the 1918 virus. In the end, the 1976 swine flu never spread beyond Fort Dix. About 500 people became sick and only one person died.

People who were most likely to become infected with the 2009 H1N1 influenza were those who had close contact with someone who is infected. The incubation period was uncertain, although it was most likely less than seven days. The disease was passed to others through infected droplets that were spread by coughing, sneezing, kissing, and close physical contact. The virus could also spread indirectly. Tests of other viral strains typically show that Type A viruses can live up to two hours on hard surfaces such as door knobs, telephones, or children's toys. This means that an infected person can leave the flu virus on objects where it can be picked up by another person who then touches his or her own mouth, nose, or eyes and becomes infected. People are contagious for about one day before symptoms appear. Adults remain contagious for about seven days after they begin to show symptoms; children can remain contagious for up to ten days.

Causes and symptoms

The 2009 H1N1 flu was caused by a newly identified strain of influenza virus. Genetic tests established that H1N1 strains encountered before that were consistent (nearing 99% genetic matches among viruses examined from patient samples taken from six countries). Of particular interest to **infectious disease** research were the genes that control hemagglutinin (H), neuraminidase (N), two surface proteins with subtypes that are numbered, hence H1N1 flu or H5N1 avian flu virus, genes that control the nucleoprotein, the surrounding matrix, and three key polymerase enzymes (designated PA, PB1, and PB2) that the virus must have to reproduce. Genetically, the 2009 H1N1 presented a mixed background, with these key genes derived from human, swine, and avian sources (a triple reassortment). The hemagglutinin produced was equidistant to the swine flu sequences found in the North America, Europe, and Asia. The neuraminidase and matrix genes sequences were close to genes found in swine flu strains found in Asia. Early evidence indicated similarities to influenza strains where the PB1 gene is of human origin and the PA and PB2 genes are from avian sources.

Symptoms of 2009 H1N1 flu were similar to the symptoms of seasonal influenza. These included **fever**, **cough**, **sore throat**, runny nose, body aches, headaches, chills, loss of appetite, and exhaustion. Some people experienced nausea, **vomiting**, and **diarrhea**. Although most cases of 2009 H1N1 flu were mild to moderate, complications such as severe pneumonia could result in **respiratory failure** and death. Neurological complications, including seizures, were also linked to 2009 H1N1 flu in children. The case fatality rate was only 0.03% compared with more than 2.5% in the Spanish flu epidemic of 1918–1919. Worldwide there may have been between 14,000 and 18,000 deaths from the H1N1 flu during the 2009 pandemic.

Diagnosis

Normally influenza is diagnosed on the basis of symptoms and the health care provider's knowledge of

WWW.BOOKBAZ.IR

KEY TERMS

Incubation period—The time between when an individual becomes infected with a disease-causing agent and when symptoms begin to appear.

Pandemic—The occurrence of a disease that in a short time infects a large percentage of the population over a wide geographical area.

Parasite—An organism that lives in or with another organism, called the host, in parasitism, a type of association characterized by the parasite obtaining benefits from the host, such as food, and the host being injured as a result.

whether influenza is prevalent in the local area. An influenza test can be performed in the doctor's office that is about 75% accurate. However, this test cannot distinguish between strains of influenza A and, therefore, was not useful in determining if the patient had H1N1 (2009). To make this determination, a mucus sample had to be sent to laboratory capable of rapid PCR analysis. Prior to May 1, 2009, only two laboratories in North America, the CDC laboratories in Atlanta and Canadian research laboratories in Winnipeg, were capable of definitively diagnosing the 2009 H1N1 flu. However, PCR machines were installed in labs in Mexico that allowed rapid definitive diagnosis.

Tests

The most accurate test for influenza is done by taking a mucus sample from the throat of an infected person. Because of the time delay involved in testing, knowing the strain of flu does not provide much help to the patient, but this information helps the CDC and WHO understand how and where flu is spreading. During an influenza pandemic, physicians often forgo laboratory confirmation of influenza, relying on signs and symptoms for diagnosis. In the United Kingdom, persons with flu symptoms are given access to **antiviral drugs** after answering questions that indicate an influenza diagnosis on a government-sponsored public health website. This saves physician resources for handling severe or emergent cases, provides quick access to treatment, and helps the person with symptoms to stay home, thereby reducing the pool of infected persons in public available to infect others.

Treatment

Supportive treatment for H1N1 (2009) appears to be the same as for all influenza viruses and included drinking plenty of fluids, extended bed rest, and use of **acetaminophen** to treat aches and fever. 2009 H1N1 influenza A virus also responded to two antiviral drugs, oseltamivir (Tamiflu) and zanamivir (Relenza). These drugs do not prevent or cure flu, but if taken within 48 hours of the start of symptoms, they reduce the severity and duration of the disease. In late April 2009, the U.S. government released stockpiled supplies of these antiviral drugs to combat 2009 H1N1 flu. Initial tests showed that 2009 H1N1 was resistant to two other antiviral drugs, amantadine (Symmetrel, Symadine), and rimantadine (Flumandine), making these drugs ineffective. **Antibiotics** also were ineffective against all viruses, including H1N1, but could be used to treat bacterial complications of influenza, such as pneumonia.

In late June 2009, public health officials in Denmark reported the first case of 2009 A/H1N1 influenza that was resistant to oseltamivir. Although some cases of resistance normally occurred and developed with seasonal influenzas, any emergence of Tamiflu-resistant 2009 A/H1N1 influenza virus put public health officials on alert for appearance of the resistant virus elsewhere. Isolated cases of Tamiflu-resistant 2009 H1N1 were identified in Japan, Hong Kong (Special Administrative Region of China), and Canada. Thus far, the Tamiflu-resistant viral influenza remained treatable with zanamivir (Relenza), the other antiviral drug usually effective against the A/H1N1 virus.

Alternatives

No scientific testing exists to validate any claim of effectiveness of any alternative medical treatments specific to H1N1 flu. Although claims of effectiveness (and/or potential harm) for any alternative medical treatment should be carefully scrutinized for supporting scientific evidence, there are a number of alternative treatments commonly used to support relief of symptoms. Because there is no scientifically validated antiviral treatment, if flu is suspected, persons should consult a physician to determine if they are in need of antiviral medicines.

Alternative practitioners recommend herbal teas to soothe the throat and allegedly boost the immune system. Other herbal treatments recommended by alternative practitioners for seasonal flu routinely include the following:

- Ginger (*Zingiber officinalis*) to reduce fever and pain, settle the stomach, and suppress cough.
- Echinacea (*Echinacea purpurea* or *angustifolia*) to reduce flu symptoms, including sore throat, chills, sweating, fatigue, weakness, body aches, and headaches.

- Cordyceps (*Cordyceps sinensis*) to modulate and allegedly boost the immune system and improve respiration.
- Eucalyptus (*Eucalyptus globulus*) or peppermint (*Mentha piperita*) essential oils added to a steam vaporizer to help clear chest and nasal congestion.

Prognosis

Because 2009 H1N1 was a new strain of influenza, it was difficult to predict the course of the disease. Generally cases were mild, but as with all flu, cases could be life-threatening if complications develop. Underlying health conditions might be worsened by the disease, and pneumonia, a common and sometimes fatal complication of seasonal flu, might develop.

Prevention

The best ways to prevent H1N1 (2009) infection are the following:

- Wash hands well and often. Hands should be washed with soap and warm water to above the wrists for 15–20 seconds or about the time it takes to sing the happy birthday song slowly. If soap and water are not available, use an alcohol-based hand sanitizer.
- Cover the mouth when coughing; dispose of used tissues in a covered container.
- Avoid touching the nose, mouth, and eyes.
- Stay home if flu symptoms appear.
- Avoid crowded places such as movie theaters.

Surgical masks are unlikely to protect against the influenza virus but are effective in reducing dissemination of droplets that can contain viral particles. Also, antiviral medications do not prevent influenza; they simply help shorten the intensity and duration of the illness.

Vaccination

The first H1N1-specific vaccine was anticipated by late September or early October 2009. World public health officials recommended prioritizing vaccine recipients according to individual risk, as well as to ensure the greatest benefit for overall public health. Pregnant women and people caring for infants, children, young people under 25 years of age, and persons with underlying health conditions such as **asthma** or diabetes were recommended to receive priority vaccination against pandemic 2009 H1N1 influenza. In addition, healthcare workers were suggested to be among the first immunized in order to keep hospitals, doctors' offices, and other critical healthcare infrastructure functional during the pandemic flu.

Public health officials acknowledged that even under the best scenarios, production of the H1N1 vaccine was expected to fall far short of global demand. As of 2009 production rates, 900 million doses of the new H1N1 vaccine could be produced each year (as two doses are required per person, enough to vaccinate 450 million people). The vaccine is produced in only a handful of countries and there were concerns these countries, along with wealthier nations, would obtain the vast majority of vaccine produced. The shortages might also hinder WHO efforts to secure donations of vaccine or agreements that will enable poorer countries to purchase vaccine at a lower price.

H-2 blockers

Definition

Histamine H-2 receptor blockers act by stopping the pathway that leads to the secretion of stomach acid. There are two kinds of pathways that react to stimulation by histamine. Histamine is produced in the body and released by mast cells in response to some types of injury or to the presence of an antigen. When histamine reaches the H-1 receptors, the reaction results in dilation of capillaries, leading to redness

WWW.BOOKBAZ.IR

and swelling, along with **itching**. These reactions can be controlled with traditional **antihistamines**.

Histamine that reaches the H-2 receptors causes increased secretion of stomach acid.

Purpose

H2 receptor blockers are used to treat conditions associated with excess amounts of stomach acid, although in some cases they have been replaced by the **proton pump inhibitors**, which have a greater effect on reducing acid secretions.

H2 receptor blockers are used to treat the following conditions:

- duodenal ulcer, as short term therapy and maintenance
- gastric ulcer, as short term therapy and maintenance
- gastroesophageal reflux disease (GERD), including endoscopically diagnosed erosive esophagitis
- pathological hypersecretory conditions such as Zollinger-Ellison syndrome, systemic mastocytosis, and multiple endocrine adenomas
- upper GI bleeding
- heartburn, acid indigestion, and sour stomach

None of the drugs in this class have been approved for use by children under the age of 12 years. However, standard pediatric texts have reported use by infants and children.

Description

There are four H2 receptor blockers on the market. Although they all work in the same manner and have similar effects, they are not all approved for the same uses.

Cimetidine (Tagamet) is available in both prescription and over-the-counter forms. The oldest of the group and the most studied, this drug is the least potent of the H2 receptor blockers, which means that higher dosages are required to provide comparable effects. There is no evidence that higher potency improves therapeutic results.

Cimetidine is the only drug in its class approved for prevention of upper gastro-intestinal bleeding. It has been reported on for a number of uses, with varying degrees of success. Cimetidine, like ranitidine, has shown some benefit in treatment of colorectal cancer. Although some claims have been made that cimetidine is useful in treatment of **acetaminophen** overdose, the evidence for this use is lacking, and cimetidine should not be used. Because cimetidine is a mild antiandrogen, it has been of some use in treatment of **hirsutism** (abnormal growth of hair on a woman's face and body).

The three other H2 receptor blockers, famotidine (Pepcid, Pepcid AC), nizatidine (Axid), and ranitidine (Zantac), are similar in their uses. All are approved for treatment of duodenal ulcer both acute treatment and maintenance therapy, gastro-esophageal reflux disease, including erosive esophagitis and gastric ulcer short term treatment, although in this group ranitidine alone is approved for maintenance treatment.

In their over-the-counter (non-prescription) forms, cimetidine and famotidine are approved for treatment of **heartburn**, acid **indigestion**, and sour stomach.

Drugs in this class are similar in other respects as well. Although study results vary, cimetidine will usually show its effects within one hour and last for about five hours after a single dose; famotidine and nizatidine also show effects within one hour but may act for up to 12 hours at maximum dosing. Ranitidine has a comparable onset of action and duration in adults but may be slower in the elderly. Onset and duration of action will vary with the individual, the dose of medication, and the presence or absence of food or **antacids** in the stomach.

When *Facts and Comparisons*, a widely used online drug information resource, compared the published reports on cure rates for duodenal **ulcers**, it found that after eight weeks of treatment, all drugs showed healing rates in the range of 82% to 95%. These results were based on comparing separate studies and did not represent comparative trials of the drugs against each other.

Recommended dosage

Cimetidine doses for patients over the age of 12 years, for oral administration.

- Short-term treatment of active duodenal ulcer: 800 mg at bedtime. Other dose regimens are sometimes used.
- Heartburn, acid indigestion, and sour stomach using the over-the-counter product: 100–200 mg with water when symptoms start. The dose may be repeated once in 24 hours.
- Prevention of heartburn, acid indigestion, and sour stomach using the over-the-counter product: 100–200 mg with water up to one hour before eating food or drinking beverages expected to cause symptoms. Dose should not exceed 400 mg in 24 hours.
- Treatment of hypersecretory conditions: 300 mg four times a day, with meals and at bedtime.
- Gastroesophageal reflux disease: 800–1,600 mg a day, divided into smaller doses. Treatment usually lasts 12 weeks.

Famotidine doses for patients over the age of 12 years, for oral administration.

- Treatment of duodenal ulcers: 40 mg once a day at bedtime. If necessary, 20 mg two times a day may be used.
- Prevention of duodenal ulcers: 20 mg once a day at bedtime.
- Gastric ulcers: 40 mg once a day at bedtime.
- To treat heartburn, acid indigestion, and sour stomach using the over-the-counter product: 10 mg with water when symptoms start. The dose may be repeated once in 24 hours.
- Hypersecretory conditions: 20 mg every six hours.
- Gastroesophageal reflux disease: 20 mg two times a day, usually for up to six weeks.

Nizatidine doses for patients over the age of 12 years, for oral administration.

- Treatment of duodenal or gastric ulcers: 300 mg once a day at bedtime. Alternately, 150 mg two times a day.
- Prevention of duodenal ulcers: 150 mg once a day at bedtime.
- Prevention of heartburn, acid indigestion, and sour stomach: 75 mg taken 30–60 minutes before meals expected to cause symptoms. The dose may be repeated once in 24 hours.
- Gastroesophageal reflux disease: 150 mg two times a day.

Ranitidine doses for patients over the age of 12 years, for oral administration.

- Duodenal ulcers, treatment: 150 mg two times a day. Alternately, 300 mg once a day at bedtime.
- Duodenal ulcers, prevention: 150 mg at bedtime.
- Gastric ulcers, treatment: 150 mg two times a day.
- Heartburn, acid indigestion, and sour stomach, treatment: 75 mg with water when symptoms start. The dose may be repeated once in 24 hours.
- Heartburn, acid indigestion, and sour stomach, prevention: 75 mg with water taken 30–60 minutes before meals or beverages expected to cause symptoms. The dose may be repeated once in 24 hours.
- Hypersecretory conditions: 150 mg two times a day.
- Gastroesophageal reflux disease: 150 mg two times a day. The dose may be increased as needed.

Precautions

Overall, the histamine H2 receptor blockers are a safe class of drugs. However, some patients may be particularly susceptible to adverse effects of these drugs. H2 receptor blockers are metabolized in the liver and excreted through the kidneys. Therefore, patients with kidney or liver problems may require reduced doses in order to maintain safe blood levels of the drugs.

Although the safety and effectiveness of H2 receptor blockers in patients over the age of 65 appears to be similar to that seen in younger patients, age-associated reductions in kidney function may lead to elevated blood levels.

Allergic reactions to these drugs are rare but have been reported.

The histamine H2 receptor blockers are **Pregnancy** category B. There are no adequate and well-controlled studies with these agents in pregnant women. Women should use them only when clearly needed and when the potential benefits outweigh the potential hazards to the fetus. Cimetidine is known to cross the placenta.

All drugs in this class are excreted into breast milk and should not be taken by nursing women. Decide whether to discontinue nursing, or discontinue the drug, taking into account the importance of the drug to the mother.

These drugs may mask the symptoms of **stomach cancer**.

Side effects

Although side effects due to the H2 receptor blockers are relatively rare and usually mild, a large number of adverse effects have been reported, in part because of the high use of these drugs. For example, the most common single adverse effect of cimetidine has been a 4% incidence of breast enlargement among males taking the drug in high doses for hypersecretory conditions. Similarly, the incidence of **headache** among high-dose cimetidine patients was 3.5%. Among patients taking lower doses, the frequency of headache was 2.1% compared to 2.3% in a placebo control group. Decreased **white blood cell count** was reported in 1 in 1,000,000 patients.

The reported side effects from the H2 receptor blocks are:

- abdominal pain
- back, leg, or stomach pain
- bleeding or crusting sores on lips
- blistering, burning, redness, scaling, or tenderness of skin
- blisters on palms of hands and soles of feet
- changes in vision or blurred vision
- coughing or difficulty in swallowing

WWW.BOOKBAZ.IR

- dark-colored urine
- dizziness
- fainting
- fast, pounding, or irregular heartbeat
- fever and/or chills
- flu-like symptoms
- general feeling of discomfort or illness
- hives
- inflammation of blood vessels
- joint pain
- light-colored stools
- mood or mental changes, including anxiety, agitation, confusion, hallucinations (seeing, hearing, or feeling things that are not there), mental depression, nervousness, or severe mental illness
- muscle cramps or aches
- nausea, vomiting, or loss of appetite
- pain
- peeling or sloughing of skin
- red or irritated eyes
- shortness of breath
- skin rash or itching
- slow heartbeat
- sore throat
- sores, ulcers, or white spots on lips, in mouth, or on genitals
- sudden difficult breathing
- swelling of face, lips, mouth, tongue, or eyelids
- swelling of hands or feet
- swollen or painful glands
- tightness in chest
- troubled breathing, unusually slow or irregular breathing
- unusual bleeding or bruising
- unusual tiredness or weakness
- wheezing
- yellow eyes or skin

Less frequently reported are

- constipation
- decreased sexual ability (especially in patients with Zollinger-Ellison disease who have received high doses of cimetidine for at least one year)
- decrease in sexual desire
- diarrhea
- difficult urination
- dizziness
- drowsiness
- dryness of mouth or skin
- headache
- increased or decreased urination
- increased sweating
- loss of hair
- ringing or buzzing in ears
- runny nose
- swelling of breasts or breast soreness in females and males
- trouble in sleeping

Not all of these adverse effects have been reported with all of the H2 receptor blockers, and some of the adverse effects may not have been drug related. However, because of the high similarity between drugs in this class, any of the reported adverse effects may be considered a possible result of therapy.

Interactions

Cimetidine and ranitidine are both metabolized in the liver using the cytochrome P450 oxidase enzyme system. Since the same enzymes metabolize many drugs, taking two or more drugs that affect the same group of enzymes may cause one of the drugs to be retained in the body longer than would have been expected. The following is a partial list of drugs that may interact with cimetidine, or to a lesser extent with ranitidine.

- benzodiazepines, including Valium, Librium and Xanax
- caffeine
- calcium channel blockers, including Adalat, Calan, Procadia, and others
- carbamazepine
- chloroquine
- labetolol
- lidocaine
- metoprolol
- metronidazole
- phenytoin
- propranolol
- quinidine
- quinine
- sulfonylureas (includes many of the drugs used to treat diabetes)
- theophyllines (used to treat asthma; Dyphylline, a member of this group, does not interact with cimetidine)

KEY TERMS

Duodenal—Pertaining to the first part of the small intestine.

Gastric—Pertaining to the stomach.

Hirsutism—Abnormal growth of hair on a woman's face and body.

Histamine—A physiologically active compound found in plant and animal tissue and released from mast cells as part of an allergic reaction in humans. It stimulates gastric secretion and causes dilation of capillaries, constriction of bronchial smooth muscle, and decreased blood pressure.

Hypersecretory—Excessive secretions, overproduction of stomach acid.

Mast cell—A cell found in connective tissue that releases substances such as heparin and histamine in response to injury or inflammation of bodily tissues.

Peptic—Induced by or associated with the action of digestive secretions.

Ulcer—A slow-healing sore on the surface of a mucous membrane, especially the membrane lining the stomach or other part of the digestive tract.

Zollinger-Ellizon syndrome—Severe peptic ulceration from excessive stomach acid production stimulated by one or more tumors that produce a powerful acid secretion.

- triamterene (a diuretic drug rarely used alone but may be found in fixed combinations, including Dyazide and Maxzide)
- tricyclic antidepressants (a group that includes amitriptyline, imipramine, and others)
- valproic acid
- warfarin

Additional drugs may also interact with the H2 receptor blockers, particularly those that might have a similar mechanism or action or adverse effects.

Hair transplantation

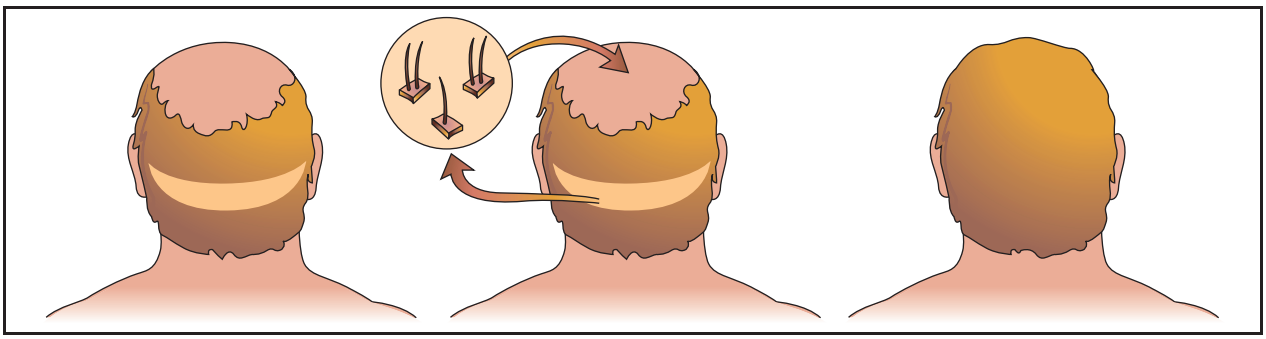
Definition

Hair transplantation is a surgical procedure used to treat baldness or hair loss (**alopecia**). Typically, tiny patches of scalp are removed from the back and sides of the head and implanted in the bald spots in the front and top of the head.

Purpose

Hair transplantation is a cosmetic procedure performed on men and occasionally on women who have significant hair loss, thinning hair, or bald spots where hair no longer grows. In men, hair loss and baldness are most commonly due to genetic factors and age. Male pattern baldness, in which the hairline gradually recedes to expose more and more of the forehead, is the most common form. Men may also experience a gradual thinning of hair at the crown or very top of the skull. For women, hair loss is more commonly due to hormonal changes and is more likely to be a thinning of hair on the entire head. Transplants can also be

WWW.BOOKBAZ.IR



The most common hair transplant procedure involves taking small strips of scalp containing hair follicles from the donor area, usually at the sides or back of the head. These strips are then divided into several hundred smaller grafts. The surgeons in the balding area by using microsurgical instruments or lasers. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

performed to replace hair lost due to **burns**, injury, or diseases of the scalp.

Demographics

An estimated 50,000 men receive hair transplants each year.

Description

Hair transplantation surgery is performed by a physician with specialty training in **plastic surgery** or, less commonly, dermatology. Each surgery lasts two to three hours, during which approximately 250 grafts will be transplanted. A moderately balding man may require up to 1,000 grafts to get good coverage of a bald area; consequently, a series of surgeries scheduled three to four months apart is usually required. Individuals may be completely awake during the procedure with just a local anesthetic applied to numb the areas of the scalp. Some persons may be given a drug to help them relax or may be given an anesthetic that puts them to sleep.

The most common transplant procedure uses a thin strip of hair and scalp from the back of the head. This strip is cut into smaller clumps of five or six hairs. Tiny slits are made in the balding area of the scalp, and a clump is implanted into each slit. The doctor performing the surgery will attempt to recreate a natural-looking hairline along the forehead. Minigrafts, micrografts, or implants of single hair follicles can be used to fill in between larger implant sites and can provide a more natural-looking hairline. The implants will also be arranged so that thick and thin hairs are interspersed and the hair will grow in the same direction.

Another type of hair replacement surgery is called scalp reduction. This involves removing some of the skin from the hairless area and "stretching" some of the nearby hair-covered scalp over the cut-away area.

Health insurance will not pay for hair transplants that are performed for cosmetic reasons. Insurance plans may pay for hair replacement surgery to correct hair loss due to accidents, burns, or disease.

It is important to be realistic about what the final result of a hair transplant will look like. This procedure does not create new hair. Rather, it simply redistributes the hair that an individual still has. Chest hair has been experimentally transplanted onto the scalp but this procedure is not widely used.

Precautions

Although hair transplantation is a fairly simple procedure, some risks are associated with any surgery. It is important to inform the physician about any medications being used and about previous allergic reactions to drugs or anesthetic agents. People with blood-clotting disorders also need to inform their physician before the procedure is performed.

Preparation

It is important to find a respected, well-established, experienced surgeon and discuss the expected results prior to the surgery. The candidate may need blood tests to check for bleeding or clotting problems and is usually asked not to take **aspirin** products before the surgery. The type of **anesthesia** used will depend on how extensive the surgery will be and the setting in which it will be performed. The candidate may be awake during the procedure but is usually given medication to induce relaxation. A local anesthetic that numbs the area will be applied or injected into the skin at the surgery sites.

KEY TERMS

Alopecia—Hair loss or baldness.

Hair follicle—A tube-like indentation in the skin from which a single hair grows.

Minigraft or micrograft—Transplantation of a small number of hair follicles, as few as one to three hairs, into a transplant site.

Transplantation—Surgically cutting out hair follicles and replanting them in a different spot on the head.

Aftercare

The areas involved in transplantation may need to be bandaged overnight. People can return to normal activities within a day. Strenuous activities should be avoided in the first few days after the surgery. On rare occasions, the implants can be ejected from the scalp during vigorous **exercise**. There may be some swelling, bruising, **headache**, and discomfort around the graft areas and around the eyes. These symptoms can usually be controlled with a mild **pain** reliever such as aspirin. Scabs may form at the graft sites and should not be scraped off. There may be some numbness at the sites, but it will diminish within two to three months.

Risks

Although there are rare cases of infection or scarring, the major risk is that the grafted area might not look the way the patient expects it to look.

Results

The transplanted hair will fall out within a few weeks; however, new hair will start to grow in the graft sites within about three months. A normal rate of hair growth is about 0.25–0.5 in. (6–13 mm) per month.

Morbidity and mortality rates

Major complications as a result of hair transplantation are extremely rare. Occasionally, a person may have problems with delayed healing, infection, scarring, or rejection of the graft, but these are uncommon.

Alternatives

There are several alternatives to hair transplantation. The two most common include use of a lotion that contains a drug preparation, or the use of a wig.

Lotions containing **minoxidil** or **finasteride** grow new hair, but it does not work for all users. The new hair minoxidil grows is usually only a light fuzz on the crown of the head. When minoxidil treatment is discontinued, the fuzz disappears, in addition to any hairs that were supposed to die during treatment. In some cases, finasteride does grow thick, strong, lengthy hair on the crown.

Wigs and hairpieces have been used for centuries. They are available in a wide price range, the more expensive ones providing a more realistic appearance than less expensive models.

Health care team roles

Hair transplantation is performed by a physician with specialty training in plastic and **cosmetic surgery** or dermatology. It may be performed in a professional office, outpatient, or hospital setting.

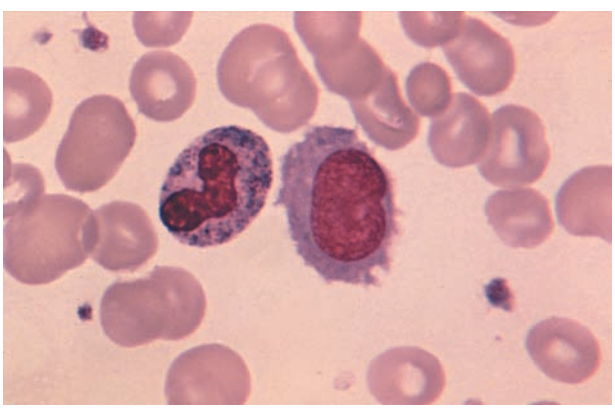
Hairy cell leukemia

Definition

Hairy cell leukemia is a disease in which a type of white blood cell called the lymphocyte, present in the blood and bone marrow, becomes malignant and proliferates. It is called hairy cell leukemia because the cells have tiny hair-like projections when viewed under the microscope.

Description

Hairy cell leukemia (HCL) is a rare cancer. It was first described in 1958 as *leukemic reticuloendotheliosis*, erroneously referring to a red blood cell because researchers were unsure of the cell of origin. It became more easily identifiable in the 1970s. There are approximately 600 new cases diagnosed every year in the United States, making up about 2% of the adult cases of leukemia each year.



A magnified image of white blood cells with "hairy" projections. *(M. Abbey/Photo Researchers, Inc.)*

HCL is found in cells located in the blood. There are three types of cells found in the blood: the red blood cells that carry oxygen to all the parts of the body; the white blood cells that are responsible for fighting infection and protecting the body from diseases; and the platelets that help in the clotting of blood. Hairy cell leukemia affects a type of white blood cell called the lymphocyte. Lymphocytes are made in the bone marrow, spleen, lymph nodes, and other organs. It specifically affects B-lymphocytes, which mature in the bone marrow. However, extremely rare variants of HCL have been discovered developing from T-lymphocytes, which mature in the thymus.

When hairy cell leukemia develops, the white blood cells become abnormal both in the way they appear (by acquiring hairy projections) and in the way they act (by proliferating without the normal control mechanisms). Further, the cells tend to accumulate in the spleen, causing it to become enlarged. The cells may also collect in the bone marrow and prevent it from producing normal blood cells. As a result, there may not be enough normal white blood cells in the blood to fight infection.

The median age at which people develop HCL is 52 years. Though it occurs in all ages, HCL more commonly develops in the older population. Men are four times more likely to develop HCL than women. There have been reports of familial aggregation of disease, with higher occurrences in Ashkenazi Jewish men. A potential genetic link is undergoing further investigation.

Causes and symptoms

The cause of hairy cell leukemia is not specifically known. However, exposure to radiation is a known cause of leukemia in general. Familial involvement is another theory, suggesting that there is a genetic component associated with this disease.

HCL is a chronic (slowly progressing) disease, and the patients may not show any symptoms for many years. As the disease advances, the patients may develop one or more of the following symptoms:

- weakness
- fatigue
- recurrent infections
- fever
- anemia
- bruising
- pain or discomfort in the abdominal area
- weight loss (uncommon)
- night sweats (uncommon)

Pain and discomfort are caused by an enlarged spleen, which results from the accumulation of the abnormal hairy cells in the spleen. Blood tests may show abnormal counts of all the different types of cells. This happens because the cancerous cells invade the bone marrow as well and prevent it from producing normal blood cells. Because of the low white cell count in the blood, the patient may have frequent infections. **Fever** often accompanies the infections. The patient is most susceptible to bacterial infections, but infections of any kind are the major cause of death. The low red cell count may cause anemia, **fatigue**, and weakness, and the low **platelet count** may cause the person to bruise and bleed easily.

Diagnosis

The doctor will palpate the abdomen and may order scans to see if the spleen is enlarged (splenomegaly). An enlarged spleen is present in 80% of patients. An enlarged liver is less common, but can occur.

If the spleen is enlarged, the doctor may order several blood tests. In these tests, the total numbers of each of the different types of blood cells (CBC) are reported. Sixty to eighty percent of patients have pancytopenia, which is a dramatic reduction in the number of red blood cells, white blood cells, and platelets circulating in the blood.

If the blood tests are abnormal, the doctor may order a **bone marrow aspiration and biopsy**. In order to establish a diagnosis, hairy cells must be present in the bone marrow.

Treatment

When physicians perform blood tests, they will determine the level of hemoglobin (the oxygen-transporting molecule of red blood cells). Serum hemoglobin levels and the size of the spleen, which can be measured on exam and by using an x ray, are proposed criteria for determining the stage of HCL. The following are the three proposed stages and their criteria:

- Stage I: Hemoglobin greater than 12 g/dL (1 g = approximately 0.02 pint and 1 dL = approximately 0.33 ounce) and spleen less than or equal to 10 cm (3.9 in).
- Stage II: Hemoglobin between 8.5 and 12 g/dL and spleen greater than 10 cm (3.9 in).
- Stage III: Hemoglobin less than 8.5 g/dL and spleen greater than 10 cm (3.9 in).

Since there is generally no accepted staging system, another method for evaluating the progression of HCL is to group patients into two categories: untreated HCL and progressive HCL, in which hairy cells are present after therapy has been administered.

Some people with hairy cell leukemia have very few or no symptoms at all, and it is reasonable to expect that 10% of patients may not need any treatment. However, if the patient is symptomatic and needs intervention, HCL is especially responsive to treatment.

There are three main courses of treatment: **chemotherapy**, **splenectomy** (surgical removal of the spleen), and immunotherapy. Once a patient meets treatment criteria, purine analogues, particularly the drugs pentostatin and cladribine, are the first-line therapy. Pentostatin is administered at 5mg/m^2 for two days every other week until total remission is achieved. Patients may experience side effects such as fever, nausea, **vomiting**, **photosensitivity**, and keratoconjuctivitis. Follow-up studies estimate a relapse-free survival rate at 76%. Cladribine (2-CdA) taken at 0.1mg/kg/day for seven days also has an impressive response. Eighty-six percent of patients experience complete remission after treatment, while 16% experience partial remission. Fever is the principal side effect of 2-CdA.

Biological therapy or immunotherapy, where the body's own immune cells are used to fight cancer, is also being investigated in clinical trials for hairy cell leukemia. A substance called interferon that is produced by the white blood cells of the body was the first systemic treatment that showed consistent results in fighting HCL. The FDA approved interferon-alpha (INF-alpha) to fight HCL. The mechanism by which INF-alpha works is not clearly understood. However, it is known that interferon stimulates the body's natural killer cells that are suppressed during HCL. The standard dosage is 2 MU/m^2 three times a week for 12 months. Side effects include fever, myalgia, malaise, **rashes**, and gastrointestinal complaints.

If the spleen is enlarged, it may be removed in a surgical procedure known as splenectomy. This usually causes a remission of the disease. However, 50% of patients that undergo splenectomy require some type of systemic treatment such as chemotherapy or immunotherapy. Splenectomy is not the most widely used course of treatment as it was many years ago. Although the spleen is not an indispensable organ, it is responsible for helping the body fight infection. Therefore, other therapies are preferred in order to salvage the spleen and its functions.

Most patients have excellent prognosis and can expect to live 10 years or longer. The disease may remain silent for years with treatment. Continual

WWW.BOOKBAZ.IR

KEY TERMS

Anemia—A condition in which there is low iron in the blood due to a deficiency of red blood cells.

Bone marrow—The spongy tissue inside the large bones in the body that is responsible for making the red blood cells, white blood cells, and platelets.

Bone marrow aspiration and biopsy—A procedure in which a needle is inserted into the large bones of the hip or spine and a small piece of marrow is removed for microscopic examination.

Immunotherapy—A mode of cancer treatment in which the immune system is stimulated to fight the cancer.

Leukemia—A disease in which the cells that constitute the blood become cancerous or abnormal.

Lymph nodes—Oval-shaped organs that are the size of peas, located throughout the body, and contain clusters of cells called lymphocytes. They filter out and destroy the bacteria, foreign particles, and cancerous cells from the blood.

Malignant—Cells that have the ability to invade locally, cause destruction of surrounding tissue, and travel to other sites in the body.

Keratoconjunctivitis—Inflammation of the conjunctiva and cornea of the eye.

Spleen—An organ that lies next to the stomach. Its function is to remove the worn-out blood cells and foreign materials from the blood stream.

Splenectomy—A surgical procedure that involves the surgical removal of the spleen.

follow-up is necessary to monitor the patient for relapse and determine true cure rates.

Alternatives

Many individuals choose to supplement traditional therapy with complementary methods. Often, these methods improve the tolerance of side effects and symptoms as well as enrich the quality of life. The American Cancer Society recommends that patients talk to their doctor to ensure that the methods they are using are safely supplementing traditional therapy. Some complementary treatments include the following:

- yoga
- meditation
- religious practices and prayer
- music therapy
- art therapy
- massage therapy
- aromatherapy

Prevention

Since the cause for the disease is unknown and there are no specific risk factors, there is no known prevention.

Halitosis *see* **Bad breath**

Hallucinations

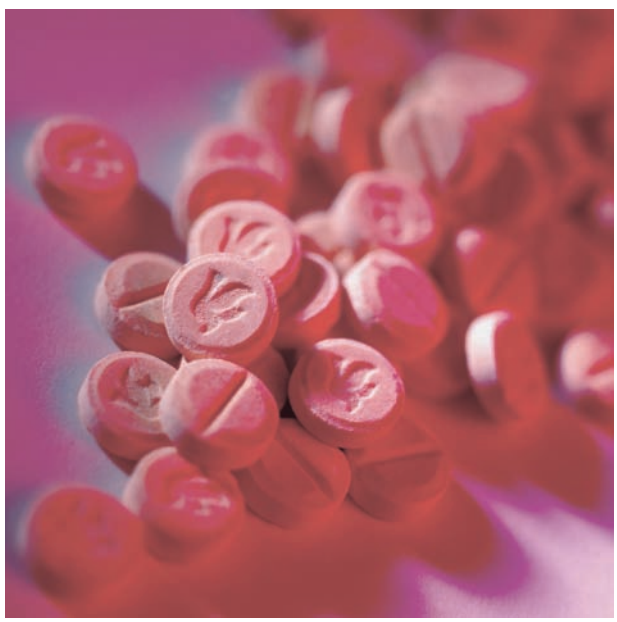
Definition

Hallucinations are false or distorted sensory experiences that appear to be real perceptions. These sensory impressions are generated by the mind rather than by any external stimuli, and may be seen, heard, felt, and even smelled or tasted.

Description

A hallucination occurs when environmental, emotional, or physical factors such as **stress**, medication, extreme **fatigue**, or mental illness cause the mechanism within the brain that helps to distinguish conscious perceptions from internal, memory-based perceptions to misfire. As a result, hallucinations occur during periods of consciousness. They can appear in the form of visions, voices or sounds, tactile feelings (known as haptic hallucinations), smells, or tastes.

Patients with **dementia** and psychotic disorders such as **schizophrenia** frequently experience hallucinations. Hallucinations can also occur in patients who are not mentally ill as a result of stress overload or exhaustion, or may be intentionally induced through the use of drugs, **meditation**, or sensory deprivation. A 1996 report published in the *British Journal of Psychiatry* noted that 37% of 4,972 people surveyed experienced hypnagogic hallucinations (hallucinations that occur as a person is falling to sleep). Hypnopomic hallucinations (hallucinations that occur just upon waking) were reported by 12% of the sample.



Ecstasy tablets. *(© Andrew Brookes/Corbis.)*

Causes and symptoms

Common causes of hallucinations include:

- Drugs. Hallucinogenics such as ecstasy (3,4-methylenedioxymethamphetamine, or MDMA), LSD (lysergic acid diethylamide, or acid), mescaline (3,4,5-trimethoxyphenethylamine, or peyote), and psilocybin (4-phosphoryloxy-N, N-dimethyltryptamine, or mushrooms) trigger hallucinations. Other drugs, such as marijuana and PCP, have hallucinatory effects. Certain prescription medications may also cause hallucinations. In addition, drug withdrawal may induce tactile and visual hallucinations as in an alcoholic experiencing delirium tremens (DTs).
- Stress. Prolonged or extreme stress can impede thought processes and trigger hallucinations.
- Sleep deprivation and/or exhaustion. Physical and emotional exhaustion can induce hallucinations by blurring the line between sleep and wakefulness.
- Meditation and/or sensory deprivation. When the brain lacks external stimulation to form perceptions, it may compensate by referencing the memory and form hallucinatory perceptions. This condition is commonly found in blind and deaf individuals.
- Electrical or neurochemical activity in the brain. A hallucinatory sensation—usually involving touch—called an aura, often appears before, and gives warning of, a migraine. Also, auras involving smell and touch (tactile) are known to warn of the onset of an epileptic attack.
- Mental illness. Up to 75% of schizophrenic patients admitted for treatment report hallucinations.
- Brain damage or disease. Lesions or injuries to the brain may alter brain function and produce hallucinations.

Diagnosis

Aside from hypnogogic and hypnopompic hallucinations, more than one event suggests a person should seek evaluation. A general physician, psychologist, or psychiatrist will try to rule out possible organic, environmental, or psychological causes through a detailed medical examination and social history. If a psychological cause such as schizophrenia is suspected, a psychologist will typically conduct an interview with the patient and his family and administer one of several clinical inventories, or tests, to evaluate the mental status of the patient.

Occasionally, people who are in good mental health will experience a hallucination. If hallucinations

WWW.BOOKBAZ.IR

KEY TERMS

Aura—A subjective sensation or motor phenomenon that precedes and indicates the onset of a neurological episode, such as a migraine or an epileptic seizure.

Hypnogogic hallucination—A hallucination, such as the sensation of falling, that occurs at the onset of sleep.

Hypnopompic hallucination—A hallucination that occurs as a person is waking from sleep.

Sensory deprivation—A situation where an individual finds himself in an environment without sensory cues. Also, (used here) the act of shutting one's senses off to outside sensory stimuli to achieve hallucinatory experiences and/or to observe the psychological results.

are infrequent and transitory and can be accounted for by short-term environmental factors such as **sleep deprivation** or meditation, no treatment may be necessary. However, if hallucinations are hampering an individual's ability to function, a general physician, psychologist, or psychiatrist should be consulted to pinpoint their source and recommend a treatment plan.

Treatment

Hallucinations that are symptomatic of a mental illness such as schizophrenia should be treated by a psychologist or psychiatrist. Antipsychotic medication such as thioridazine (Mellaril), haloperidol (Haldol), chlorpromazine (Thorazine), clozapine (Clozaril), or risperidone (Risperdal) may be prescribed.

Prognosis

In many cases, chronic hallucinations caused by schizophrenia or some other mental illness can be controlled by medication. If hallucinations persist, psychosocial therapy can be helpful in teaching the patient the coping skills to deal with them. Hallucinations due to sleep deprivation or extreme stress generally stop after the cause is removed.

Hammertoe

Definition

Hammertoe is a condition in which the toe is bent in a claw-like position. It can be present in more than one toe but is most common in the second toe.

Description

Hammertoe is described as a deformity in which the toes bend downward with the toe joint usually enlarged. Over time, the joint enlarges and stiffens as it rubs against shoes. Other foot structures involved include the overlying skin and blood vessels and nerves connected to the involved toes.

Causes and symptoms

The shortening of tendons responsible for the control and movement of the affected toe or toes cause hammertoe. Top portions of the toes become callused from the friction produced against the inside of shoes. This common foot problem often results from improper fit of footwear. This is especially the case with high-heeled shoes placing pressure on the front part of the foot that compresses the smaller toes tightly together. The condition frequently stems from muscle imbalance, and usually leaves the affected individual with impaired balance.

Diagnosis

A thorough medical history and physical exam by a physician is always necessary for the proper diagnosis of hammertoe and other foot conditions. Because the condition involves bony deformity, x rays can help to confirm the diagnosis.

Hammertoe most commonly affects the second toe which, as shown, often develops a corn over the deformity. *(Custom Medical Stock Photo, Inc.)*

Treatment

Conservative

Wearing proper footwear and stockings with plenty of room in the toe region can provide treatment for hammertoe. Stretching exercises may be helpful in lengthening the excessively tight tendons.

Surgery

In advanced cases where conservative treatment is unsuccessful, surgery may be recommended. The tendons that attach to the involved toes are located and an incision is made to free the connective tissue to the foot bones. Additional incisions are made so the toes no longer bend in a downward fashion. The middle joints of the affected toes are connected permanently with surgical hardware such as pins and wire sutures. The incision is then closed with fine sutures. These sutures are removed approximately 7–10 days after surgery.

Alternatives

Various soft tissue and joint treatments offered by **chiropractic** and **massage therapy** may be useful to decrease the tightness of the affected structures.

Prognosis

If detected early, hammertoe can be treated non-surgically. If surgery becomes necessary, surgical risks are minimal with the overall outcome providing good results.

Prevention

Wearing comfortable shoes that fit well can prevent many foot ailments. Foot width may increase with age. Feet should always be measured before buying shoes. The upper part of the shoes should be made of a soft, flexible material to match the shape of the foot. Shoes made of leather can reduce the possibility of skin irritations. Soles should provide solid footing and not be slippery. Thick soles lessen pressure when walking on hard surfaces. Low-heeled shoes are more comfortable, safer, and less damaging than high-heeled shoes.

Hand–foot–and–mouth disease

Definition

Hand–foot–and–mouth disease is an infection of young children in which characteristic fluid–filled blisters appear on the hands, feet, and inside the mouth.

Demographics

Hand–foot–and–mouth disease is very common among young children and often occurs in clusters of children who are in daycare together.

An outbreak of hand–foot–and–mouth disease occurred in Singapore in 2000, with more than 1,000 diagnosed cases, all in children, resulting in four deaths. A smaller outbreak occurred in Malaysia in 2000. In 1998, a serious outbreak of enterovirus 71 in Taiwan resulted in more than one million cases of hand–foot–and–mouth disease. Of these, there were 405 severe cases and 78 deaths, 71 of which were children younger than five years of age.

Hand–foot–and–mouth should not be confused with foot and mouth disease, which infects cattle

WWW.BOOKBAZ.IR

Skin lesions on the tongue and around the mouth of a five-year-old boy due to hand-foot-mouth disease. *(Dr. P. Marazzi/ Photo Researchers, Inc.)*

but is extremely rare in humans. An outbreak of foot and mouth disease swept through Great Britain and into other parts of Europe and South America in 2001.

Description

Coxsackie viruses belong to a family of viruses called enteroviruses. These viruses live in the gastrointestinal tract and are present in feces. They can be spread easily from one person to another when poor hygiene allows the virus within the feces to be passed from person to person. After exposure to the virus, development of symptoms takes only four to six days. Hand–foot–and–mouth disease can occur year–round, although the largest number of cases are in summer and fall months.

Causes and symptoms

Hand–foot–and–mouth disease is very common among young children and often occurs in clusters of children who are in daycare together. It is spread when poor hand–washing after a diaper change or contact with saliva (drool) allows the virus to be passed from one child to another.

Within about four to six days of acquiring the virus, an infected child may develop a relatively low–grade **fever**, ranging from 99–102°F (37–38.9°C). Other symptoms include **fatigue**, loss of energy, decreased appetite, and a sore sensation in the mouth that may interfere with feeding. After one to two days, fluid–filled bumps (vesicles) appear on the inside of the mouth, along the surface of the tongue, on the roof of the mouth, and on the insides of the cheeks. These are tiny blisters, about 0.12–0.28 in (3–7 mm) in diameter. Eventually, they may appear on the palms of the hands and on the soles of the feet. Occasionally, these vesicles may occur in the diaper region.

The vesicles in the mouth cause the majority of discomfort, and the child may refuse to eat or drink due to **pain**. This phase usually lasts for an average of a week. As long as the bumps have clear fluid within them, the disease is at its most contagious. The fluid within the vesicles contains large quantities of the causative viruses. Extra care should be taken to avoid contact with this fluid.

Diagnosis

Diagnosis is made by most practitioners solely on the basis of the unique appearance of blisters of the mouth, hands, and feet in a child not appearing very ill.

Treatment

There are no treatments available to cure or decrease the duration of the disease. Medications like **acetaminophen** or ibuprofen may be helpful for decreasing pain, and allowing the child to eat and drink. It is important to try to encourage the child to take in adequate amounts of fluids, in the form of ice chips or popsicles if other foods or liquids are too uncomfortable.

Alternatives

There are no effective alternative treatments for hand–foot–and–mouth disease.

Prognosis

The prognosis for a child with hand–foot–and–mouth disease is excellent. The child is usually completely better within about a week of the start of the illness.

Prevention

Prevention involves careful attention to hygiene. Thorough, consistent hand–washing practices and discouraging the sharing of clothes, towels, and stuffed toys are all helpful. The virus continues to be passed in the feces for several weeks after infection, so good hygiene should be practiced long after all signs of infection have passed.

KEY TERMS

Enteroviruses—Viruses which live in the gastrointestinal tract. Coxsackie viruses, viruses that cause hand–foot–mouth disease, are an enterovirus.

Vesicle—A bump on the skin filled with fluid.

Hantavirus infections

Definition

Hantavirus infection is caused by a group of viruses that can infect humans with two serious illnesses: hemorrhagic **fever** with renal syndrome (HFRS), and Hantavirus pulmonary syndrome (HPS).

Description

Hantaviruses are found without causing symptoms within various species of rodents and are passed to humans by exposure to the urine, feces, or saliva of those infected rodents. Ten different hantaviruses have been identified as important in humans. Each is found in specific geographic regions and is spread by different rodent carriers. Further, each type of virus causes a slightly different form of illness in its human hosts:

- Hantaan virus is carried by the striped field mouse and exists in Korea, China, Eastern Russia, and the Balkans. Hantaan virus causes a severe form of hemorrhagic fever with renal syndrome (HFRS).
- Puumula virus is carried by bank voles and exists in Scandinavia, western Russia, and Europe. Puumula virus causes a milder form of HFRS, usually termed *nephropathia epidemica*.
- Seoul virus is carried by a type of rat called the Norway rat and exists worldwide, but causes disease almost exclusively in Asia. Seoul virus causes a form of HFRS that is slightly milder than that caused by Hantaan virus, but results in liver complications.
- Prospect Hill virus is carried by meadow voles and exists in the United States, but has not been found to cause human disease.
- Sin Nombre virus, the most predominant strain in the United States, is carried by the deer mouse. This virus was responsible for severe cases of HPS that occurred in the southwestern United States in 1993.
- Black Creek Canal virus has been found in Florida. It is predominantly carried by cotton rats.
- New York virus strain has been documented in New York State. The vectors for this virus seem to be deer mice and white-footed mice.
- Bayou virus has been reported in Louisiana and Texas and is carried by the marsh rice rat.
- Blue River virus has been found in Indiana and Oklahoma and seems to be associated with the white-footed mouse.
- Monongahela virus, discovered in 2000, has been found in Pennsylvania and is transmitted by the white-footed mouse.

Causes and symptoms

Hemorrhagic fever with renal syndrome (HFRS)

Hantaviruses that produce forms of hemorrhagic fever with renal syndrome (HFRS) cause a classic group of symptoms, including fever, malfunction of the kidneys, and low **platelet count**. Because platelets are blood cells important in proper clotting, low numbers of circulating platelets can result in spontaneous bleeding, or hemorrhage.

Patients with HFRS have **pain** in the head, abdomen, and lower back and may report bloodshot eyes and blurry vision. Tiny pinpoint hemorrhages, called petechiae, may appear on the upper body and the soft

WWW.BOOKBAZ.IR

palate in the mouth. The patient's face, chest, abdomen, and back often appear flushed and red, as if sunburned.

After about five days, the patient may have a sudden drop in blood pressure; often it drops low enough to cause the clinical syndrome called **shock**. Shock is a state in which blood circulation throughout the body is insufficient to deliver proper quantities of oxygen. Lengthy shock can result in permanent damage to the body's organs, particularly the brain, which is very sensitive to oxygen deprivation.

Around day eight of HFRS, kidney involvement results in multiple derangements of the body chemistry. Simultaneously, the hemorrhagic features of the illness begin to cause spontaneous bleeding, as demonstrated by bloody urine, bloody vomit, and in very serious cases, brain hemorrhages with resulting changes in consciousness.

Day 11 often brings further chemical derangements, with associated confusion, **hallucinations**, seizures, and lung complications. Those who survive this final phase usually begin to turn the corner toward recovery at this time, although recovery takes approximately six weeks.

Hantavirus pulmonary syndrome (HPS)

Hantavirus pulmonary syndrome (HPS) develops in four stages. They are:

- The incubation period. This lasts from one to five weeks from exposure. Here, the patient may exhibit no symptoms.
- The prodrome, or warning signs, stage. Symptoms begin with a fever, muscle aches, headache, dizziness, and abdominal pain and upset. Sometimes there is vomiting and diarrhea.
- The cardiopulmonary stage. The patient slips into this stage rapidly, sometimes within a day or two of initial symptoms, sometimes as long as 10 days later. There is a drop in blood pressure, shock, and leaking of the blood vessels of the lungs, which results in fluid accumulation in the lungs, and subsequent shortness of breath. The fluid accumulation can be so rapid and so severe as to put the patient in respiratory failure within only a few hours. Some patients experience severe abdominal tenderness.
- The convalescent stage. If the patient survives the respiratory complications of the previous stage, there is a rapid recovery, usually within a day or two. However, abnormal liver and lung functioning may persist for six months.

KEY TERMS

Hemodialysis—A method of mechanically cleansing the blood outside of the body, in order to remove various substances that would normally be cleared by the kidneys. Hemodialysis is used when an individual is in relative, or complete, kidney failure.

Hemorrhagic—A condition resulting in massive, difficult-to-control bleeding.

Petechiae—Pinpoint size red spots caused by hemorrhaging under the skin.

Platelets—Circulating blood cells that are crucial to the mechanism of clotting.

Prodrome—Early symptoms or warning signs

Pulmonary—Referring to the lungs.

Renal—Referring to the kidneys.

Shock—Shock is a state in which blood circulation is insufficient to deliver adequate oxygen to vital organs.

Diagnosis

Serologic techniques help diagnose a hantavirus infection. The patient's blood is drawn, and the ELISA (enzyme-linked immunosorbent assay) is done in a laboratory to identify the presence of specific immune substances (antibodies)—substances which an individual's body would only produce in response to the hantavirus.

It is very difficult to demonstrate the actual virus in human tissue or to grow cultures of the virus within the laboratory, so the majority of diagnostic tests use indirect means to demonstrate the presence of the virus.

Treatment

Treatment of hantavirus infections is primarily supportive because there are no agents available to kill the viruses and interrupt the infection. Broad-spectrum **antibiotics** are given until the diagnosis is confirmed. Supportive care consists of providing treatment in response to the patient's symptoms. Because both HFRS and HPS progress so rapidly, patients must be closely monitored so that treatment may be started at the first sign of a particular problem. Low blood pressure is treated with medications. Blood transfusions are given for both hemorrhage and shock states. Hemodialysis is used in kidney

failure. (Hemodialysis involves mechanically cleansing the blood outside of the body, to replace the kidney's normal function of removing various toxins form the blood.) Rapid respiratory assistance is critical, often requiring intubation.

The anti-viral agent ribavirin has been approved for use in early treatment of hantavirus infections.

Prognosis

The diseases caused by hantaviruses are extraordinarily lethal. About 6–15% of people who contract HFRS have died. Almost half of all people who contract HPS will die. This gives HPS one of the highest fatality rates of any acute viral disease. It is essential that people living in areas where the hantaviruses exist seek quick medical treatment should they begin to develop an illness that might be due to a hantavirus.

Prevention

There are no immunizations currently available against any of the hantaviruses. In 2003, developments in genetic science were helping researchers work on a possible **vaccination** and therapy for several versions of hantavirus, including the Sin Nombre virus that causes HPS. With further work, a gene-based vaccine could become available in the future. However, the only known forms of hantavirus prevention involve rodent control within the community and within individual households. The following is a list of preventive measures:

- Avoiding areas known to be infested by rodents is essential.
- Keeping a clean home and keeping food in rodent-proof containers.
- Disposing of garbage and emptying pet food dishes at night.
- Setting rodent traps around baseboards and in tight places. Disposing of dead animals with gloves and disinfecting the area with bleach.
- Using rodenticide as necessary.
- Sealing any entry holes 0.25 in (6 mm) wide or wider around foundations with screen, cement, or metal flashing.
- Clearing brush and junk from house foundations.
- Putting metal flashing around house foundations.
- Elevating hay, woodpiles, and refuse containers.
- Airing out all sealed outbuildings or cabins 30 minutes before cleaning for the season.
- When camping, avoiding sleeping on the bare ground. It is advised to sleep on a cot or in a tent with a floor.

Haptoglobin test

Definition

This test is done to help evaluate a person for **hemolytic anemia**.

Purpose

Haptoglobin is a blood protein made by the liver. The haptoglobin levels decrease in hemolytic anemia. Hemolytic **anemias** include a variety of conditions that result in hemolyzed, or burst, red blood cells.

Decreased values can also indicate a slower type of red cell destruction unrelated to anemia. For example, destruction can be caused by mechanical heart valves or abnormal hemoglobin, such as **sickle cell disease** or **thalassemia**.

Haptoglobin is known as an acute phase reactant. Its level increases during acute conditions such as infection, injury, tissue destruction, some cancers, **burns**, surgery, or **trauma**. Its purpose is to remove damaged cells and debris and rescue important material such as iron. Haptoglobin levels can be used to monitor the course of these conditions.

Description

Hemoglobin is the protein in the red blood cell that carries oxygen throughout the body. Iron is an essential part of hemoglobin; without iron, hemoglobin can not function. Haptoglobin's main role is to save iron by attaching itself to any hemoglobin released from a red cell.

When red blood cells are destroyed, the hemoglobin is released. Haptoglobin is always present in the blood waiting to bind to released hemoglobin. White blood cells (called macrophages) bring the haptoglobin-hemoglobin complex to the liver, where

WWW.BOOKBAZ.IR

the haptoglobin and hemoglobin are separated and the iron is recycled.

In hemolytic anemia, so many red cells are destroyed that most of the available haptoglobin is needed to bind the released hemoglobin. The more severe the hemolysis, the less haptoglobin remains in the blood.

Haptoglobin is measured in several different ways. One way is called rate nephelometry. A person's serum is mixed with a substance that will bind to haptoglobin. The amount of bound haptoglobin is measured using a rate nephelometer, which measures the amount of light scattered by the bound haptoglobin. Another way of measuring haptoglobin is to measure it according to how much hemoglobin it can bind.

Preparation

This test requires 5 mL of blood. The person being tested should avoid taking **oral contraceptives** or androgens before this test. A healthcare worker ties a tourniquet on the person's upper arm, locates a vein in the inner elbow region, and inserts a needle into that vein. Vacuum action draws the blood through the needle into an attached tube. Collection of the sample takes only a few minutes.

Aftercare

Discomfort or bruising may occur at the puncture site or the person may feel dizzy or faint. Pressure to the puncture site until the bleeding stops reduces bruising. Warm packs to the puncture site relieve discomfort.

Normal results

Normal results vary based on the laboratory and test method used. Haptoglobin is not present in newborns at birth, but develop adult levels by six months.

Abnormal results

Decreased haptoglobin levels usually indicates hemolytic anemia. Other causes of red cell destruction also decrease haptoglobin: a blood **transfusion** reaction; mechanical heart valve; abnormally shaped red cells; or abnormal hemoglobin, such as thalassemia or sickle cell anemia.

Haptoglobin levels are low in **liver disease**, because the liver can not manufacture normal amounts of haptoglobin. Low levels may also indicate an inherited lack of haptoglobin, a condition found particularly in African Americans.

KEY TERMS

Acute phase reactant—A substance in the blood that increases as a response to an acute condition such as infection, injury, tissue destruction, some cancers, burns, surgery, or trauma.

Haptoglobin—A blood protein made by the liver. Its main role is to save iron by attaching itself to any hemoglobin released from a red cell.

Hemoglobin—The protein in the red blood cell that carries oxygen.

Hemolytic anemia—A variety of conditions that result in hemolyzed, or burst, red blood cells.

Haptoglobin increases as a reaction to illness, trauma, or rheumatoid disease. High haptoglobin values should be followed up with additional tests. Drugs can also effect haptoglobin levels.

Normal results vary widely from person to person. Unless the level is very high or very low, haptoglobin levels are most valuable when the results of several tests done on different days are compared.

Hartnup disease

Definition

Hartnup disease is an inherited nutritional disorder with primary symptoms including a red, scaly rash and sensitivity to sunlight.

Description

Hartnup disease was first identified in the 1950s in the Hartnup family in London. A defect in intestines and kidneys makes it difficult to break down and absorb protein in the diet. This causes a condition very similar to pellegra (niacin deficiency). The condition occurs in about one of every 26,000 live births.

Causes and symptoms

Hartnup disease is an in-born error of metabolism, that is, a condition where certain nutrients cannot be digested and absorbed properly. The condition is passed on genetically in families. It occurs when a person inherits two recessive genes for the disease, one from each parent. People with Hartnup disease are not able to absorb some of the amino acids (the smaller building blocks that make up proteins) in their intestines. One of the amino acids that is not well absorbed is tryptophan, which the body uses to make its own form of niacin.

The majority of people with this disorder do not show any symptoms. About 10–20% of people with Hartnup disease do have symptoms. The most prominent symptom is a red, scaly rash that gets worse when the patient is exposed to sunlight. **Headache**, **fainting**, and **diarrhea** may also occur. Intellectual disabilities (ID), cerebral ataxia (muscle weakness), and **delirium** (a confused, agitated, delusional state) are some of the more serious complications that can occur. Short stature has also been noted in some patients. Although this is an inherited disease, the development of symptoms depends on a variety of factors including diet, environment, and other genetic traits controlling amino acid levels in the body. Symptoms can be brought on by exposure to sunlight, **fever**, drugs, or other stresses. Poor **nutrition** frequently precedes an attack of symptoms. The frequency of attacks usually decreases as the patient gets older.

Diagnosis

The symptoms of this disease suggest a deficiency of a B vitamin called niacin. A detailed diet history can be used to assess if there is adequate protein and **vitamins** in the diet. The diagnosis of Hartnup disease is confirmed by a laboratory test of the urine, which will contain an abnormally high amount of amino acids (aminoaciduria).

Treatment

The vitamin niacin is given as a treatment for Hartnup disease. The typical dosage ranges from 40–200 mg of nicotinamide (a form of niacin) per day to prevent pellagra-like symptoms. Some patients may require dietary supplements of tryptophan.

Eating a healthy, high protein diet can relieve the symptoms and prevent them from recurring.

KEY TERMS

Amino acids—Proteins are made up of organic compounds called amino acids. The human body uses amino acids to build and repair body tissue. The body can make some of its own amino acids from other nutrients in the diet; these are called non-essential amino acids. Essential amino acids are those that cannot be made by the body but must be consumed in the diet. Animal proteins (like meat, eggs, fish, and milk) provide all of the amino acids.

Aminoaciduria—A condition confirmed by laboratory tests where high levels of amino acids are found in the urine.

Pellegra—A condition caused by a dietary deficiency of one of the B vitamins called niacin.

Tryptophan—An essential amino acid that has to consumed in the diet because it cannot be manufactured by the body. Tryptophan is converted by the body to niacin, one of the B vitamins.

Prognosis

The prognosis for a healthy life is good once the condition has been identified and treated.

Prevention

Hartnup disease is an inherited condition. Parents may not have the disease themselves, but may pass the genes responsible for it on to their children. **Genetic testing** can be used to identify carriers of the genes. Symptoms can usually be controlled with a high protein diet, vitamin supplements of niacin, and by avoiding the stresses that contribute to attacks of symptoms.

Hatha yoga

Definition

Hatha **yoga** is the most widely practiced form of yoga in the United States. It is the branch of yoga that concentrates on physical health and mental well-being. Hatha yoga uses bodily postures (*asanas*), breathing techniques (*pranayama*), and **meditation** (*dyana*) with the goal of bringing about a sound, healthy body and a clear, peaceful mind. There are nearly 200 hatha yoga postures, with hundreds of variations, which work to make the spine supple and to promote circulation in all the organs, glands, and tissues. Hatha yoga postures also stretch and align the body, promoting balance and flexibility.

Purpose

In a celebrated 1990 study, *Dr. Dean Ornish's Program for Reversing Heart Disease* (Random House), a cardiologist showed that yoga and meditation combined with a low-fat diet and group support could significantly reduce the blockage of coronary arteries. Other studies have shown yoga's benefit in reducing stress-related problems such as high blood pressure and **cholesterol**. Meditation has been adopted by medical schools and clinics as an effective stress management technique. Hatha yoga is also used by physical therapists to improve many injuries and disabilities, as the gentleness and adaptability of yoga make it an excellent **rehabilitation** program.

Yoga has been touted for its ability to reduce problems with such varying conditions as **asthma**, backaches, diabetes, **constipation**, **menopause**, **multiple sclerosis**, **varicose veins**, and **carpal tunnel syndrome**. A vegetarian diet is the dietary goal of yoga, and this change of lifestyle has been shown to significantly increase longevity and reduce **heart disease**.

Yoga as a daily **exercise** program can improve fitness, strength, and flexibility. People who practice yoga correctly every day report that it can promote high levels of overall health and energy. The mental component of yoga can clarify and discipline the mind, and yoga practitioners say its benefits can permeate all facets of a person's life and attitude, raising self-esteem and self-understanding.

Description

Origins

Yoga was developed in ancient India as far back as 5,000 years ago; sculptures detailing yoga positions have been found in India dating back to 3000 B.C. Yoga is derived from a Sanskrit word which means "union." The goal of classical yoga is to bring self-transcendence, or enlightenment, through physical, mental and spiritual health. Many people in the West mistakenly believe yoga to be a religion, but its teachers point out that it is a system of living designed to promote health, peace of mind, and deeper awareness of ourselves. There are several branches of yoga, each of which is a different path and philosophy toward self-improvement. Some of these paths include service to others, pursuit of wisdom, non-violence, devotion to God, and observance of spiritual rituals. Hatha yoga is the path that has physical health and balance as a primary goal, for its practitioners believe that greater mental and spiritual awareness can be brought about with a healthy and pure body.

The origins of hatha yoga have been traced back to the eleventh century A.D. The Sanskrit word *ha* means "sun" and *tha* means "moon," and thus, hatha, or literally sun-moon yoga, strives to balance opposing parts of the physical body, the front and back, left and right, top and bottom. Some yoga masters (*yogis*) claim that hatha yoga was originally developed by enlightened teachers to help people survive during the Age of Kali, or the spiritual dark ages, in which Hindus believe we are now living.

The original philosophers of yoga developed it as an eight-fold path to complete health. These eight steps include moral and ethical considerations (such as honesty, non-aggression, peacefulness, non-stealing, generosity, and sexual propriety), self-discipline (including purity, simplicity, devotion to God, and self-knowledge), posture, breath control, control of desires, concentration, meditation, and happiness. According to yogis, if these steps are followed diligently, a person can reach high levels of health and mental awareness.

As it has subsequently developed, hatha yoga has concentrated mainly on two of the eight paths, breathing and posture. Yogis believe breathing to be the most important metabolic function; we breathe roughly 23,000 times per day and use about 4,500

gallons of air, which increases during exercise. Thus, breathing is extremely important to health, and *prana*, or life-force, is found most abundantly in the air and in the breath. If we are breathing incorrectly, we are hampering our potential for optimal health. *Pranayama*, literally the "science of breathing" or "control of life force," is the yogic practice of breathing correctly and deeply.

In addition to breathing, hatha yoga utilizes asanas, or physical postures, to bring about flexibility, balance and strength in the body. Each of these postures has a definite form and precise steps for achieving the desired position and for exiting it. These postures, yogis maintain, have been scientifically developed to increase circulation and health in all parts of the body, from the muscular tissues to the glands and internal organs. Yogis claim that although hatha yoga can make the body as strong and fit as any exercise program, its real benefits come about because it is a system of maintenance and balance for the whole body.

Yoga was brought to the United States in the late 1800s, when Swami Vivekananda, an Indian yogi, presented a lecture on yoga in Chicago. Hatha yoga captured the imagination of the Western mind, because accomplished yogis could demonstrate incredible levels of fitness, flexibility, and control over their bodies and metabolism. Yoga has flourished in the West. Americans have brought to yoga their energy and zest for innovation, which troubles some Indian yogis and encourages others, as new variations and schools of yoga have developed. For instance, power yoga is a recent Americanized version of yoga, which takes hatha yoga principles and speeds them up into an extremely rigorous aerobic workout, and many strict hatha yoga teachers oppose this sort of change to their philosophy. Other variations of hatha yoga in the United States now include Iyengar, Ashtanga, Kripalu, Integral, Viniyoga, Hidden Language, and Bikram yoga, to name a few. Sivananda yoga was practiced by Lilias Folen, who was responsible for introducing many Americans to yoga through public television.

Iyengar yoga was developed by B.K.S. Iyengar, who is widely accepted as one of the great living yogis. Iyengar uses classical hatha yoga asanas and breathing techniques, but emphasizes great precision and strict form in the poses and uses many variations on a few postures. Iyengar allows the use of props such as belts, ropes, chairs, and blocks to enable students to get into postures they otherwise could not. In this respect, Iyengar yoga is good for **physical therapy** because it assists in the manipulation of inflexible or injured areas.

Ashtanga yoga, made popular by yogi K. Patabhi Jois, also uses hatha yoga asanas, but places an emphasis on the sequences in which these postures are performed. Ashtanga routines often unfold like long dances with many positions done quickly one after the other. Ashtanga is thus a rigorous form of hatha yoga, and sometimes can resemble a difficult aerobic workout. Ashtanga teachers claim that this form of yoga uses body heat, sweating, and deep breathing to purify the body.

Kripalu yoga uses hatha yoga positions but emphasizes the mental and emotional components of each asana. Its teachers believe that tension and long-held emotional problems can be released from the body by a deep and meditative approach to the yoga positions. Integral yoga seeks to combine all the paths of yoga and is generally more meditative than physical, emphasizing spirituality and awareness in everyday life. Viniyoga tries to adapt hatha yoga techniques to each individual body and medical problem. Hidden Language yoga was developed by Swami Sivananda Radha, a Western man influenced by Jungian psychology. It emphasizes the symbolic and psychological parts of yoga postures and techniques. Its students are encouraged to write journals and participate in group discussions as part of their practice. Bikram yoga has became very popular in the late 1990s, as its popular teacher, Bikram Choudury, began teaching in Beverly Hills and has been endorsed by many famous celebrities. Bikram yoga uses the repetition of 26 specific poses and two breathing techniques to stretch and tone the whole body.

A hatha yoga routine consists of a series of physical postures and breathing techniques. Routines can take anywhere from 20 minutes to two hours, depending on the needs and ability of the practitioner. Yoga should always be adapted to one's state of health; that is, a shorter and easier routine should be used when a person is fatigued. Yoga is ideally practiced at the same time every day, to encourage the discipline of the practice. It can be done at any time of day; some prefer it in the morning as a wake-up routine, while others like to wind down and de-stress with yoga at the end of the day.

Yoga asanas consist of three basic movements: backward bends, forward bends, and twisting movements. These postures are always balanced; a back bend should be followed with a forward bend, and a leftward movement should be followed by one to the right. Diaphragm breathing is important during

WWW.BOOKBAZ.IR

KEY TERMS

Asana—Yoga posture or stance.

Diaphragm breathing—Method of deep breathing using the entire lungs.

Dyana—Yoga meditation.

Meditation—Technique of mental relaxation.

Prana—Yoga term for life-enhancing nutrient found in air, food, and water.

Pranayama—Yoga method of breathing.

the poses, where the breath begins at the bottom of the lungs. The stomach should move outward with the inhalation and relax inward during exhalation. The breath should be through the nose at all times during hatha asanas. Typically, one inhales during backward bends and exhales during forward bending movements.

The mental component in yoga is as important as the physical movements. Yoga is not a competitive sport, but a means to self-awareness and self-improvement. An attitude of attention, care, and non-criticism is important; limitations should be acknowledged and calmly improved. Patience is important, and yoga stretches should be slow and worked up to gradually. The body should be worked with, and never against, and a person should never overexert. A yoga stretch should be done only so far as proper form and alignment of the whole body can be maintained. Some yoga stretches can be uncomfortable for beginners, and part of yoga is learning to distinguish between sensations that are beneficial and those that can signal potential injury. A good rule is that positions should be stopped when there is sharp **pain** in the joints, muscles, or tendons.

Preparations

All that is needed to perform hatha yoga is a flat floor and adequate space for stretching out. A well-ventilated space is preferable, for facilitating proper breathing technique. Yoga mats are available that provide non-slip surfaces for standing poses. Loose, comfortable clothing should be worn. Yoga should be done on an empty stomach; a general rule is to wait three hours after a meal.

Yoga is an exercise that can be done anywhere and requires no special equipment. Yoga uses only gravity and the body itself as resistance, so it is a low-impact activity excellent for those who do not do well with other types of exercise. The mental component of yoga can appeal to those who get bored easily with exercise. By the same token, yoga can be a good stress management tool for those who prefer movement to sitting meditation.

Precautions

As with any exercise program, people should check with their doctors before starting yoga practice for the first time. Those with medical conditions, injuries, or spinal problems should find a yoga teacher familiar with their conditions before beginning yoga. Pregnant women, particularly after the third month of **pregnancy**, should only perform a few yoga positions with the supervision of an experienced teacher. Some yoga asanas can be very difficult, and potentially injurious, for beginners, so teachers should always be consulted as preparation for advanced yoga positions. Certain yoga positions should not be performed by those with fevers or during menstruation.

Side effects

Those just beginning hatha yoga programs often report **fatigue** and soreness throughout the body, as yoga stretches and exercises muscles and tendons that are often long-neglected. Some yogic breathing and meditation techniques can be difficult for beginners and can cause **dizziness** or disorientation; these are best performed under the guidance of a teacher.

Head and neck cancer

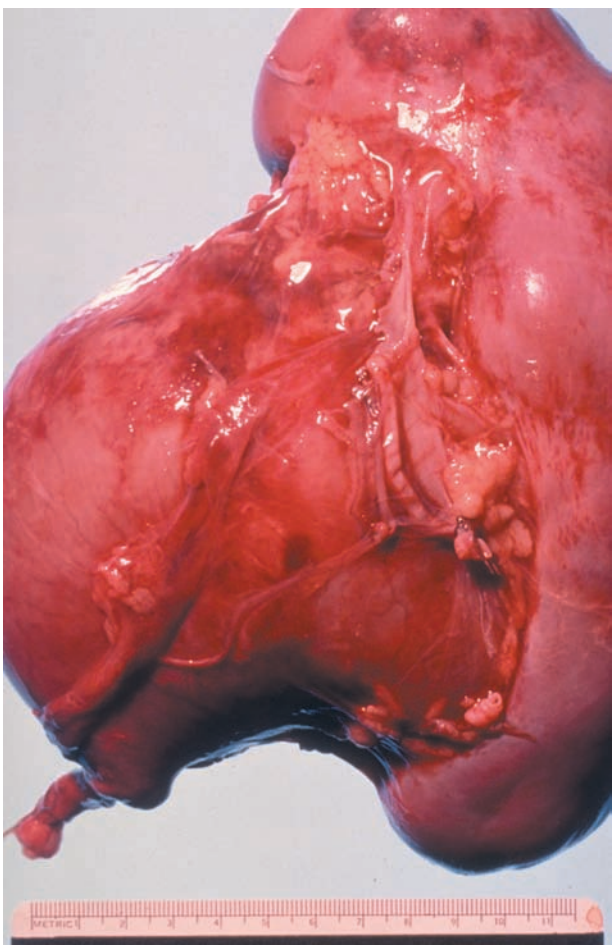
Definition

The term "head and neck cancers" refers to a group of cancers found in the head and neck region, excluding tumors of the eyes and the thyroid gland, and tumors that originate in the brain.

Tumors classified as head and neck tumors are found in:

- The oral cavity (mouth). The lips, the tongue, the teeth, the gums, the lining inside the lips and cheeks, the floor of the mouth (under the tongue), the roof of the mouth and the small area behind the wisdom teeth are all included in the oral cavity.
- The oropharynx, which includes the back one-third of the tongue, the back of the throat, and the tonsils.
- The nasopharynx, which includes the area behind the nose.
- The hypopharynx, the lower part of the throat.
- The larynx (voice box, located in front of the neck, in the region of the Adam's apple). In the larynx, the cancer can occur in any of the three regions: the glottis (location of the vocal cords); the supraglottis (the area above the glottis); and the subglottis (the area that connects the glottis to the windpipe).
- The paranasal sinuses, which include the ethmoid and maxillary sinuses.
- The salivary glands.

The most frequently occurring cancers of the head and neck area are oral cancers and laryngeal cancers. Almost half of all the head and neck cancers occur in the oral cavity, and a third of the cancers are found in the larynx. By definition, the term "head and neck cancers" usually excludes tumors that occur in the brain.



A specimen of a squamous cell carcinoma of the tongue and jaw. *(Custom Medical Stock Photo, Inc.)*

Description

The tumors associated with head and neck cancers are found in several regions, including the lips, tongue, mouth, nasal passages, pharynx, larynx (voice box), and salivary gland. Many head and neck cancers interfere with the functions of eating and breathing. Laryngeal cancer affects speech. Because the loss of any of these functions is significant, early detection and appropriate treatment are of utmost importance.

Roughly 3% of all cancers in the United States develop in the oral cavity, pharyngeal area or in the larynx. The most common cancers of the head and neck area are oral cancers and laryngeal cancers. Half of all head and neck cancers occur in the oral cavity and pharynx and almost 20% originate in the larynx. With regard to the total number of head and neck cancers, the National Cancer Institute (NCI) estimates that between 52,000 and 55,000 men and women (40,220 men and 14,850 women) in this country are diagnosed with head and neck cancers each year and that 12,000 (8,600 men and 3,400 women) die from the disease. The American Cancer Society estimates that about 37,000 new cases of oral cavity and pharyngeal cancers will be diagnosed in the United States in the year 2014 and that 7,300 people will die from them. The estimated number of cases worldwide is about 450,000.

The numbers of new cases and deaths from laryngeal and oral cancers have been steadily decreasing in the last three decades. This decrease is attributed to the decrease in smoking. The demographics of oral cancer are changing, however, with nonsmokers

WWW.BOOKBAZ.IR

below the age of 50 being the fastest-growing group among people recently diagnosed with oral cancer. It is thought that the spread of human papillomavirus (HPV) among younger people is a major factor in this demographic shift.

Causes and symptoms

Risk factors

Tobacco is regarded as the single greatest risk factor contributing to the occurrence of oral and laryngeal cancer: 75–80% of these patients are smokers. Heavy alcohol use has also been included as a risk factor. A combination of tobacco and alcohol use increases the risk for oral cancer by 6 to 15 times more than for users of either substance alone. Exposure to asbestos appears to increase the risk of developing laryngeal cancer. Infection with human papillomavirus (HPV)—particularly HPV16—is a recently recognized risk factor for oral cancer. Oral HPV infection is more common in men than in women. The risk of oral HPV infection is linked to such sexual behaviors as open mouth kissing and oral-genital contact (oral sex). The risk of HPV16 infection also increases with the number of a person's sexual partners.

About 7% of oral cancers are thought to result from a genetic predisposition; two inherited syndromes linked to an increased risk of oral cancer are Fanconi anemia and dyskeratosis congenita. A family history of oral cancer is an additional risk factor for the disease. Other factors that increase the risk of oral cancer include poor oral hygiene; poor nutrition; gastroesophageal reflux disease (GERD); disorders of the immune system, including HIV infection; or taking medications following organ transplantation that weaken the immune system.

The risk of both oral cancer and laryngeal cancer seems to increase with age. Most of the cases occur in individuals over 40 years of age, and the average age at diagnosis is 60. While oral cancer is diagnosed in men twice as often as it does women, laryngeal cancer is four times more common in men than in women. Both diseases are more common in African Americans than among Caucasians.

In the case of lip cancer, just like skin cancer, exposure to sun over a prolonged period has been shown to increase the risk. In Southeast Asian countries (India and Sri Lanka), chewing of betel nuts has been associated with cancer of the lining of the cheek. An increased incidence of nasal cavity cancer has been observed among furniture workers, probably due to the inhalation of wood dust. A virus (Epstein-Barr) has been shown to cause nasopharyngeal cancer.

Symptoms

There are many types of head and neck cancers. Signs and symptoms of the various types of cancer are often specific to the original location of the cancer.

- Oral cancers occur in the mouth, or oral cavity, which includes the lips, the lining inside the lips and cheeks (the buccal area), the front two-thirds of the tongue, the teeth, the gums, the floor of the mouth (under the tongue), the roof of the mouth, and the small area behind the wisdom teeth. Symptoms and signs include a mouth sore that does not heal within two weeks; white or red patches on the oral mucosa (leukoplakia and erythroplakia); unusual bleeding from the teeth or gums; or a lump on the gums, mouth, or tongue.
- Lip cancers occur on the inside or outside surface of the lips. Signs of this cancer include a lump on the inside of the lip or a sore on the outside, which is usually a form of skin cancer.
- Oropharyngeal cancer is found on the back one-third of the tongue, the upper section of the pharynx, and the area around the tonsils. Symptoms include a lump in the back of the mouth or throat, ear pain, or difficulty swallowing.
- Nasopharyngeal cancer is found in the area behind the nose and the upper section of the pharynx, the area just behind the mouth. Symptoms include difficulty breathing or speaking, pain or ringing in ears, frequent headaches, or trouble hearing.
- Hypopharyngeal cancer is found only in the lower portion of the pharynx. Symptoms include a sore throat that does not subside, difficulty swallowing, a lump in the neck, or ear pain.
- Laryngeal cancer starts in the larynx, which is located in the front of the neck in the region of the Adam's apple. Symptoms include pain when swallowing, a sore throat that does not subside, a change in voice, or ear pain.
- Paranasal sinus cancer and nasal cancer develop in the small hollow spaces in the nose called the sinuses and in the nasal cavity, which is the passageway for air moving to the throat during breathing. Symptoms include frequent sinus infections, nosebleeds, a sore inside the nose that does not heal, or pain in the sinus area.
- Salivary gland tumors form in the salivary glands, which produce saliva to help prevent the mouth from drying out and to aid with digestion. They are located under the jaw, in front of the ears, underneath the tongue, and in other regions of the digestive tract. Symptoms include swelling under the chin or around the jawbone, facial numbness, inability to move the facial muscles, or persistent pain in the face, chin, or neck.

When detected early and treated appropriately, head and neck cancers have an excellent chance of being cured completely.

Diagnosis

Specific diagnostic tests used depend on the location of the cancer. The standard tests are:

Physical examination

The first step in diagnosis is a complete and thorough examination of the oral and nasal cavity, using mirrors and other visual aids. This examination may be performed by the patient's dentist or by an otolaryngologist, a doctor who specializes in disorders of the ear, nose, and throat. The tongue and the back of the throat are examined as well. Any suspicious looking lumps or lesions are examined with fingers (palpation). In order to look inside the larynx, the doctor may sometimes perform a procedure known as laryngoscopy. In indirect laryngoscopy, the doctor looks down the throat with a small, long handled mirror. Sometimes the doctor inserts a lighted tube (laryngoscope or a fiberoptic scope) through the patient's nose or mouth. As the tube goes down the throat, the doctor can observe areas that cannot be seen by a simple mirror. This procedure is called a direct laryngoscopy. Sometimes patients may be given a mild sedative to help them relax, and a local anesthetic to ease any discomfort. An endoscopic examination under anesthesia may also be required as part of the work-up for head and neck cancer.

Blood tests

The doctor may order blood or other immunological tests. These tests are aimed at detecting antibodies to the Epstein-Barr virus, which has been known to cause cancer of the nasopharynx.

Imaging tests

X rays of the mouth, the sinuses, the skull, and the chest region may be required. Computed tomography scans (CT scan), a procedure in which a computer takes a series of x-ray pictures of areas inside the body, and/or magnetic resonance imaging (MRI) and positron emission tomography (PET scans) may be ordered. Patients with cancers of the nasopharynx may also undergo imaging tests with PET scans and/or CT scans to determine the presence of distant metastatic lesions. A positron emission tomography or PET scan involves the injection of a radioactive sugar into the patient's blood. Cancers take up sugar at a higher rate than normal tissue and therefore will emit higher levels of radioactivity that can be detected by the PET scanner. Some machines are designed to perform a CT scan and a PET scan at the same time. A bone scan may be done in patients with advanced cancer to determine whether the cancer has spread to the bones.

Dental, speech, and swallowing evaluations may also be conducted.

Biopsy

When a sore does not heal or a suspicious patch or lump is seen in the mouth, larynx, nasopharynx, or throat, a biopsy may be performed to rule out the possibility of cancer. The biopsy is the most definitive diagnostic tool for detecting the cancer. If cancerous cells are detected in the biopsied sample, the doctor may perform more extensive tests in order to find whether, and to where, the cancer may have spread.

Treatment

Cancers of the head and neck can be treated successfully if diagnosed early. The choice of treatment depends on the size of the tumor, its location, and whether it has spread to other parts of the body.

In the case of lip and mouth cancers, sometimes surgery is performed to remove the cancer. Radiation therapy, which destroys the cancerous cells, is also one of the primary modes of treatment and may be used alone or in combination with surgery. If lip surgery is drastic, rehabilitation cosmetic or reconstructive surgery may be considered. Cancers of the oral cavity may be treated by a newer form of pharmacotherapy called targeted therapy (or biologic therapy), which uses drugs that block the growth of cancer cells by targeting specific molecules that the cancer cells need for growth and reproduction. The targeted drug used most often to treat oral cancer is cetuximab, which may be combined with radiation therapy for earlier-stage cancers or with cisplatin for advanced-stage oral cancers. Cetuximab works by targeting the epidermal growth factor receptor (EGFR), a protein on the surface of certain cells that helps them grow and divide. Cancers of the oral cavity usually have larger than normal amounts of EGFR, so they can be effectively treated with cetuximab. Other drugs that target EGFR are currently under investigation as treatments for oral cancer.

Cancers of the nasal cavity are often diagnosed late because they have no specific symptoms in their early stages or the symptoms may just resemble chronic sinusitis. Treatment is often complex, involving a combination of radiotherapy and surgery. Surgery is generally recommended for small tumors. If the

WWW.BOOKBAZ.IR

cancer cannot be removed by surgery, radiotherapy is used alone.

Treatment of oropharyngeal cancers (cancers that are either in the back of the tongue, the throat, or the tonsils) generally involves radiation therapy and/or surgery. Cancers of the oropharynx may be treated as of 2014 by resection using trans-oral robotic surgery or TORS. In the past, these cancers were difficult to treat with open surgery on the throat because of post-operative complications. TORS, however, allows the surgeon to remove cancerous tissue from the oropharynx through the mouth without having to open the throat. After aggressive surgery and radiation, rehabilitation is often necessary and is an essential part of the treatment. The patient may experience difficulties with swallowing, chewing, and speech and may require a team of health care workers, including speech therapists, prosthodontists, occupational therapists, dietitians, and social workers.

Cancers of the nasopharynx are different from the other head and neck cancers in that there does not appear to be any association between alcohol and tobacco use and the development of the cancer. In addition, the incidence is seen primarily in two age groups: young adults and 50–70 year-olds. The Epstein-Barr virus has been implicated as the causative agent in most patients. While 80–90% of small tumors are curable by radiation therapy, advanced tumors that have spread to the bone and cranial nerves are difficult to control. Surgery is not very helpful and is rarely attempted. Radiation remains the only treatment of choice to treat the cancer that has metastasized (traveled) to the lymph nodes in the neck.

In the case of cancer of the larynx, radiotherapy is the first choice to treat small lesions. This is done in an attempt to preserve the voice. If the cancer recurs later, surgery may be attempted. If the cancer is limited to one of the two vocal cords, laser excision surgery is used. In order to treat advanced cancers, a combination of surgery and radiation therapy is often used. Because the chances of a cure in the case of advanced laryngeal cancers are rather low with current therapies, the patient may be advised to participate in clinical trials so they may get access to new experimental drugs and procedures, such as chemotherapy, that are being evaluated.

When only part of the larynx is removed, a relatively slight change in the voice may occur—the patient may sound slightly hoarse. However, in a total laryngectomy, the entire voice box is removed. The patients then have to re-learn to speak using different approaches, such as esophageal speech, tracheo-esophageal (TE) speech, or by means of an artificial larynx.

In esophageal speech, the patients are taught how to create a new type of voice by forcing air through the esophagus (food pipe) into the mouth. This method has a high success rate of approximately 65% and patients are even able to go back to jobs that require a high level of verbal communication, such as telephone operators and salespersons.

In the second approach, TE speech, a small opening called a fistula is created surgically between the trachea (breathing tube to the lungs) and the esophagus (tube that connects the throat to the stomach) to carry air into the throat. A small tube, known as the "voice prosthesis," is placed in the opening of the fistula to keep it open and to prevent food and liquid from going down into the trachea. In order to talk, the stoma (or the opening made at the base of the neck) must be covered with one's thumb during exhalation. As the air is forced out from the trachea into the esophagus, it vibrates the walls of the esophagus. This produces a sound that is then modified by the lips and tongue to produce normal sounding speech.

In the third approach, an artificial larynx (a battery-driven vibrator) is placed on the outside of the throat. Sound is created as air passes through the stoma (opening made at the base of the neck) and the mouth forms words.

Prognosis

Oral cavity

With early detection and immediate treatment, survival rates can be dramatically improved. For lip and oral cancer, if detected in their early stages, almost 90% of the patients survive five years or more. When diagnosed in advanced stages, however, the 5-year survival rate drops to a mere 20%.

Nose and sinuses

Cancers of the nasal cavity often go undetected until they reach an advanced stage. If diagnosed at the early stages, the five-year survival rates are about 63%. However, if cancers are more advanced, only 30% of the patients survive five years or more.

Oropharynx

In cancer of the oropharynx, 60–80% of the patients survive five years or more if the cancer is

KEY TERMS

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Buccal—Pertaining to the mouth or cheeks. It is derived from the Latin word for cheek.

Chemotherapy—Treatment of cancer with synthetic drugs that destroy the tumor either by inhibiting the growth of the cancerous cells or by killing the cancer cells.

Clinical trials—Highly regulated and carefully controlled patient studies, where either new drugs to treat cancer or novel methods of treatment are investigated.

Computerized tomography scan (CT scan)—A medical procedure where a series of X-rays are taken and put together by a computer in order to form detailed pictures of areas inside the body.

Erythroplakia—A flat red patch or lesion in the mouth.

Laryngoscopy—A medical procedure that uses flexible, lighted, narrow tubes inserted through the mouth or nose to examine the larynx and other areas deep inside the neck.

Leukoplakia—A flat whitish-colored area of the oral mucosa that is not caused by thrush or any other specific disease.

Magnetic resonance imaging (MRI)—A medical procedure used for diagnostic purposes where pictures of areas inside the body can be created using a magnet linked to a computer.

Otolaryngologist—A physician who diagnoses and treats disorders of the head and neck; sometimes called an ear, nose, and throat specialist or ENT.

Prosthesis—An artificial device used to replace a missing body part.

Prosthodontist—A dentist with specialized training in restoring dental function after surgery and making dental prostheses.

Radiation therapy—Treatment using high energy radiation from x-ray machines, cobalt, radium, or other sources.

Resection—Surgical removal of a tumor.

Stoma—An artificial opening created by surgery in the throat or abdomen that connects a body cavity to the outside environment.

Ultrasonogram—A procedure in which high-frequency sound waves that cannot be heard by human ears are bounced off internal organs and tissues. These sound waves produce a pattern of echoes that are then used by the computer to create sonograms, or pictures, of areas inside the body.

X rays—High-energy radiation used in high doses, either to diagnose or treat disease.

detected in the early stages. As the cancer advances, the survival rate drops to 15–30%.

Nasopharynx

Patients who are diagnosed with early-stage cancers that have originated in the nasopharynx have an excellent chance of a complete cure (almost 95%). Unfortunately, most of the time, the patients are in an advanced stage at the time of initial diagnosis. With newer chemotherapy drugs, the 5-year survival rate has improved and 5–40% of the patients survive five years or longer.

Larynx

Small cancers of the larynx have an excellent five-year survival rate of 75–95%. However, as with most of the head and neck cancers, the survival rates drop dramatically as the cancer advances. Only 15–25% of the patients survive five years or more after being initially diagnosed with advanced laryngeal cancer.

Prevention

Refraining from the use of all tobacco products (cigarettes, cigars, pipe tobacco, chewing tobacco), consuming alcohol in moderation, and practicing good oral hygiene are some of the measures that one can take to lower the risk of head and neck cancers. Better education of the public is important, as knowledge regarding the risk factors of head and neck cancers is limited as of 2014. Only 25% of U.S. adults can detect early signs of abnormal oral cavity; and only 13% understand the implications of regular alcohol consumption in developing oral cancer. Cancer prevention and control programs are growing rapidly with screening services for high-risk populations, health promotion, education, and intervention strategies.

WWW.BOOKBAZ.IR

Because there is an association between excessive exposure to the sun and lip cancer, people who spend a lot of time outdoors in the sun should protect themselves from the sun's harmful rays. Regular physical examinations, or mouth examination by patients themselves, or by the patient's doctor or dentist, can help detect oral cancer in its very early stages.

Because working with asbestos has been shown to increase one's risk of getting cancer of the larynx, asbestos workers should follow safety rules to avoid inhaling asbestos fibers. Also, malnutrition and vitamin deficiencies have been shown to have some association with an increased incidence of head and neck cancers. The American Cancer Society recommends eating a healthy diet, consisting of at least five servings of fruits and vegetables every day, and six servings of food from other plant sources such as cereals, breads, grain products, rice, pasta and beans. Reducing one's intake of high-fat food from animal sources is also advised.

Head injury

Definition

Injury to the head may damage the scalp, skull, or brain. The most important consequence of head **trauma** is **traumatic brain injury**. Head injury may occur either as a closed head injury, such as the head hitting a car's windshield, or as a penetrating head injury, as when a bullet pierces the skull. Both may cause damage that ranges from mild to profound. Very severe injury can be fatal because of profound brain damage.

Causes of intracranial pressure

- Aneurysm rupture
- Brain tumor
- Encephalitis
- Head injury
- Hydrocephalus
- Hypertensive brain hemorrhage
- Intraventricular hemorrhage
- Meningitis
- Subdural hematoma
- Status epilepticus
- Stroke

Description

External trauma to the head is capable of damaging the brain, even if there is no external evidence of damage. More serious injuries can cause skull fracture, **blood clots** between the skull and the brain, or bruising and tearing of the brain tissue itself.

Injuries to the head can be caused by traffic accidents, **sports injuries**, falls, workplace accidents, assaults, or bullets. Most people have had some type of head injury at least once in their lives, but rarely do they require a hospital visit.

Each year about two million people have a serious head injury and up to 750,000 of them are severe enough to require hospitalization. Brain injury is most likely to occur in males between ages 15 and 24, usually as a result of car and motorcycle accidents. About 70% of all accidental deaths are due to head injuries, as are most of the disabilities that occur after trauma.

A person who has had a head injury and who is experiencing the following symptoms should seek medical care immediately:

- serious bleeding from the head or face
- loss of consciousness, however brief
- confusion and lethargy
- lack of pulse or breathing
- clear fluid drainage from the nose or ear

WWW.BOOKBAZ.IR

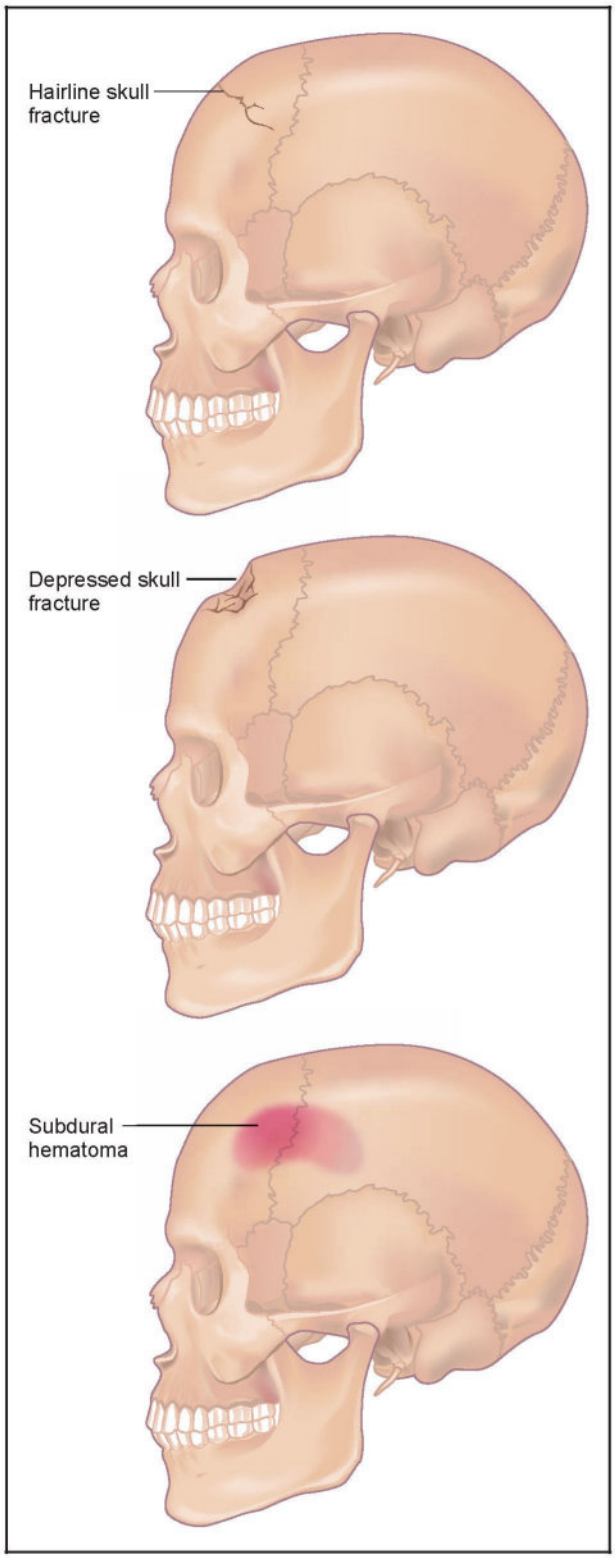

Illustration depicting three types of head injury: hairline fracture, depressed fracture, and subdural hematoma. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Causes and symptoms

A head injury may cause damage both from the direct physical injury to the brain and from secondary factors, such as lack of oxygen, brain swelling, and disturbance of blood flow. Both closed and penetrating head injuries can cause swirling movements throughout the brain, tearing nerve fibers and causing widespread bleeding or a blood clot in or around the brain. Swelling may raise pressure within the skull (intracranial pressure) and may block the flow of oxygen to the brain.

Head trauma may cause a **concussion**, in which there is a brief loss of consciousness without visible structural damage to the brain. In addition to loss of consciousness, initial symptoms of brain injury may include:

- memory loss and confusion
- vomiting
- dizziness
- partial paralysis or numbness
- shock
- anxiety

After a head injury, there may be a period of impaired consciousness followed by a period of confusion and impaired memory with disorientation and a breakdown in the ability to store and retrieve new information. Others experience temporary **amnesia** following head injury that begins with **memory loss** over a period of weeks, months, or years before the injury (retrograde amnesia). As the patient recovers, memory slowly returns. Post-traumatic amnesia refers to loss of memory for events during and after the accident.

Epilepsy occurs in 2–5% of people who have had a head injury; it is much more common in people who have had severe or penetrating injuries. Most cases of epilepsy appear right after the accident or within the first year and become less likely with increased time following the accident.

Closed head injury

Closed head injury refers to brain injury without any penetrating injury to the brain. It may be the result of a direct blow to the head; of the moving head being rapidly stopped, such as when a person's head hits a windshield in a car accident; or by the sudden deceleration of the head without its striking another object. The kind of injury the brain receives in a closed head injury is determined by whether or not the head was unrestrained upon impact and the direction, force, and velocity of the blow. If the head is resting on impact, the maximum damage will be found at the impact site. A moving head will cause a "contrecoup injury" where

the brain damage occurs on the side opposite the point of impact, as a result of the brain slamming into that side of the skull. A closed head injury also may occur without the head being struck, such as when a person experiences **whiplash**. This type of injury occurs because the brain is of a different density than the skull and can be injured when delicate brain tissues hit against the rough, jagged inner surface of the skull.

Penetrating head injury

If the skull is fractured, bone fragments may be driven into the brain. Any object that penetrates the skull may implant foreign material and dirt into the brain, leading to an infection.

Skull fracture

A skull fracture is a medical emergency that must be treated promptly to prevent possible brain damage. Such an injury may be obvious if blood or bone fragments are visible, but it is possible for a fracture to have occurred without any apparent damage. A skull fracture should be suspected if there is:

- blood or clear fluid leaking from the nose or ears
- unequal pupil size
- bruises or discoloration around the eyes or behind the ears
- swelling or depression of part of the head

Intracranial hemorrhage

Bleeding (hemorrhage) inside the skull may accompany a head injury and cause additional damage to the brain. A blood clot (hematoma) may occur if a blood vessel between the skull and the brain ruptures; when the blood leaks out and forms a clot, it can press against brain tissue, causing symptoms from a few hours to a few weeks after the injury. If the clot is located between the bones of the skull and the covering of the brain (dura), it is called an epidural hematoma. If the clot is between the dura and the brain tissue itself, the condition is called a **subdural hematoma**. In other cases, bleeding may occur deeper inside the brain. This condition is called intracerebral hemorrhage or intracerebral contusion (from the word for bruising).

In any case, if the blood flow is not stopped, it can lead to unconsciousness and death. The symptoms of bleeding within the skull include:

- nausea and vomiting
- headache
- loss of consciousness
- unequal pupil size
- lethargy

A three-dimensional computed tomography (CT) scan of a human skull showing a depressed skull fracture above the right eye. *(Custom Medical Stock Photo, Inc.)*

Post-concussion syndrome

If the head injury is mild, there may be no symptoms other than a slight **headache**. There also may be confusion, **dizziness**, and blurred vision. While the head injury may seem to have been quite mild, in many cases symptoms persist for days or weeks. Up to 60% of patients who sustain a mild brain injury continue to experience a range of symptoms called "post-concussion syndrome," as long as six months or a year after the injury.

The symptoms of **post-concussion syndrome** can result in a puzzling interplay of behavioral, cognitive, and emotional complaints that can be difficult to diagnose, including:

- headache
- dizziness
- mental confusion

WWW.BOOKBAZ.IR

- behavior changes
- memory loss
- cognitive deficits
- depression
- emotional outbursts

Diagnosis

The extent of damage in a severe head injury can be assessed with computed tomography (CT) scan, **magnetic resonance imaging** (MRI), **positron emission tomography** (PET) scans, electroencephalograms (EEG), and routine neurological and neuropsychological evaluations.

Doctors use the Glasgow **Coma** Scale to evaluate the extent of brain damage based on observing a patient's ability to open his or her eyes, respond verbally, and respond to stimulation by moving (motor response). Patients can score from 3 to 15 points on this scale. People who score below eight when they are admitted usually have a severe brain injury and will need rehabilitative therapy as they recover. In general, higher scores on the Glasgow Coma Scale indicate less severe brain injury and a better prognosis for recovery.

Patients with a mild head injury who experience symptoms are advised to seek out the care of a specialist; unless a family physician is thoroughly familiar with medical literature in this newly emerging area, experts warn that there is a good chance that patient complaints after a mild head injury will be downplayed or dismissed. In the case of mild head injury or post-concussion syndrome, CT and MRI scans, electroencephalograms (EEG), and routine neurological evaluations all may be normal because the damage is so subtle. In many cases, these tests cannot detect the microscopic damage that occurs when fibers are stretched in a mild, diffuse injury. In this type of injury, the axons lose some of their covering and become less efficient. This mild injury to the white matter reduces the quality of communication between different parts or the brain. A PET scan, which evaluates cerebral blood flow and brain metabolism, may be of help in diagnosing mild head injury.

Patients with continuing symptoms after a mild head injury should call a local chapter of a head-injury foundation that can refer patients to the best nearby expert.

Treatment

If a concussion, bleeding inside the skull, or skull fracture is suspected, the patient should be kept quiet in a darkened room, with head and shoulders raised slightly on a pillow or blanket.

After initial emergency treatment, a team of specialists may be needed to evaluate and treat the problems that result. A penetrating wound may require surgery. Those with severe injuries or with a deteriorating level of consciousness may be kept hospitalized for observation. If there is bleeding inside the skull, the blood may need to be surgically drained; if a clot has formed, it may need to be removed. Severe skull **fractures** also require surgery.

Supportive care and specific treatments may be required if the patient experiences further complications. People who experience seizures, for example, may be given **anticonvulsant drugs**, and people who develop fluid on the brain (**hydrocephalus**) may have a shunt inserted to drain the fluid.

In the event of long-term disability as a result of head injury, there are a variety of treatment programs available, including long-term **rehabilitation**, coma treatment centers, transitional living programs, behavior management programs, life-long residential or day treatment programs and independent living programs.

Prognosis

Prompt, proper diagnosis and treatment can help alleviate some of the problems after a head injury. It usually is difficult to predict the outcome of a brain injury in the first few hours or days; a patient's prognosis may not be known for many months or even years.

The outlook for someone with a minor head injury generally is good, although recovery may be delayed and symptoms such as headache, dizziness, and cognitive problems can persist for up to a year or longer after an accident. This can limit a person's ability to work and cause strain in personal relationships.

Serious head injuries can be devastating, producing permanent mental and physical disability. Epileptic seizures may occur after a severe head injury, especially a penetrating brain injury, a severe skull fracture, or a serious brain hemorrhage. Recovery from a severe head injury can be very slow, and it may take five years or longer to heal completely. Risk factors associated with an increased likelihood of memory problems or seizures after head injury include age, length and depth of coma, duration of post-traumatic and retrograde amnesia, presence of focal brain injuries, and initial Glasgow Coma Scale score.

As researchers learn more about the long-term effects of head injuries, they have started to uncover links to later conditions. A 2003 report found that

KEY TERMS

Computed tomography scan (CT)—A diagnostic technique in which the combined use of a computer and x rays produce clear cross-sectional images of tissue. It provides clearer, more detailed information than x rays alone.

Electroencephalogram (EEG)—A record of the tiny electrical impulses produced by the brain's activity. By measuring characteristic wave patterns, the EEG can help diagnose certain conditions of the brain.

Magnetic resonance imaging (MRI)—A diagnostic technique that provides high quality cross-sectional images of organs within the body without x rays or other radiation.

Positron emission tomography (PET) scan—A computerized diagnostic technique that uses radioactive substances to examine structures of the body. When used to assess the brain, it produces a three-dimensional image that reflects the metabolic and chemical activity of the brain.

mild brain injury during childhood could speed up expression of **schizophrenia** in those who were already likely to get the disorder because of genetics. Those with a history of a childhood brain injury, even a minor one, were more likely to get familial schizophrenia than a sibling and to have earlier onset. Another study in 2003 found that people who had a history of a severe head injury were four times more likely to develop Parkinson's disease than the average population. Those requiring hospitalization for their head injuries were 11 times as likely. The risk did not increase for people receiving mild head injuries.

Prevention

Many severe head injuries could be prevented by wearing protective helmets during certain sports or when riding a bike or motorcycle. Seat belts and airbags can prevent many head injuries that result from car accidents. Appropriate protective headgear always should be worn on the job where head injuries are a possibility.

Headache

Definition

A headache involves **pain** in the head that can arise from many disorders or may be a disorder in and of itself.

WWW.BOOKBAZ.IR

Description

There are three types of primary headaches: tension-type (muscular contraction headache), migraine (vascular headaches), and cluster. Virtually everyone experiences a tension-type headache at some point. An estimated 18% of American women suffer migraines, compared to 6% of men. Cluster headaches affect fewer than 0.5% of the population, and men account for approximately 80% of all cases. Headaches caused by illness are secondary headaches and are not included in these numbers.

Approximately 40–45 million people in the United States have chronic headaches. Headaches have an enormous impact on society due to missed workdays and productivity losses.

Causes and symptoms

Traditional theories about headaches link tension-type headaches to muscle contraction, and migraine and cluster headaches to blood vessel dilation (swelling). Pain-sensitive structures in the head include blood vessel walls, membranous coverings of the brain, and scalp and neck muscles. Brain tissue itself has no sensitivity to pain. Therefore, headaches may result from contraction of the muscles of the scalp, face or neck; dilation of the blood vessels in the head; or brain swelling that stretches the brain's coverings. Involvement of specific nerves of the face and head may also cause characteristic headaches. Sinus inflammation is a common cause of headache. Keeping a headache diary may help link headaches to stressful occurrences, menstrual phases, food triggers, or medication.

Tension-type headaches are often brought on by **stress**, overexertion, loud noise, and other external factors. The typical tension-type headache is described as a tightening around the head and neck, and an accompanying dull ache.

Migraines are intense throbbing headaches occurring on one or both sides of the head, usually on one side. The pain is accompanied by other symptoms such as nausea, **vomiting**, blurred vision, and aversion to light, sound, and movement. Migraines often are triggered by food items, such as red wine, chocolate, and aged cheeses. For women, a hormonal connection is likely, since headaches occur at specific points in the menstrual cycle, with use of **oral contraceptives**, or the use of **hormone replacement therapy** after **menopause**. Research shows that a complex interaction of nerves and neurotransmitters in the brain act to cause migraine headaches.

Cluster headaches cause excruciating pain. The severe, stabbing pain centers around one eye, and eye tearing and nasal congestion occur on the same side. The headache lasts from 15 minutes to four hours and may recur several times in a day. Heavy smokers are more likely to suffer cluster headaches, which also are associated with alcohol consumption.

Diagnosis

Since headaches arise from many causes, a physical exam assesses general health and a neurologic exam evaluates the possibility of neurologic disease as a cause for the headache. If the headache is the primary illness, the doctor asks for a thorough history of the headache. Questions revolve around its frequency and duration, when it occurs, pain intensity and location, possible triggers, and any prior symptoms. This information aids in classifying the headache.

Warning signs that should point out the need for prompt medical intervention include:

- "Worst headache of my life." This may indicate subarachnoid hemorrhage from a ruptured aneurysm (swollen blood vessel) in the head or other neurological emergency.
- Headache accompanied by one-sided weakness, numbness, visual loss, speech difficulty, or other signs. This may indicate a stroke. Migraines may include neurological symptoms.
- Headache that becomes worse over a period of six months, especially if most prominent in the morning or if accompanied by neurological symptoms. This may indicate a brain tumor.
- Sudden onset of headache. If accompanied by fever and stiff neck, this can indicate meningitis.

Headache diagnosis may include neurological imaging tests such as computed tomography scan (CT scan) or **magnetic resonance imaging** (MRI).

Treatment

Headache treatment is divided into two forms: abortive and prophylactic. Abortive treatment addresses a headache in progress, and prophylactic treatment prevents headache occurrence.

Tension-type headaches can be treated with **aspirin**, **acetaminophen**, ibuprofen, or naproxen. In early 1998, the FDA approved extra-strength Excedrin, which includes **caffeine**, for mild migraines. Physicians continue to investigate and monitor the best treatment for migraines and generally prefer a stepped approach, depending on headache severity, frequency, and impact on the patient's quality of life. A group of drugs called

KEY TERMS

Abortive—Referring to treatment that relieves symptoms of a disorder.

Analgesics—A class of pain-relieving medicines, including aspirin and Tylenol.

Biofeedback—A technique in which a person is taught to consciously control the body's response to a stimulus.

Chronic—Referring to a condition that occurs frequently or continuously or on a regular basis.

Prophylactic—Referring to treatment that prevents symptoms of a disorder from appearing.

Transcutaneous electrical nerve stimulation—A method that electrically stimulates nerve and blocks the transmission of pain signals, called TENS.

triptans are usually preferred for abortive treatment. About seven triptans are available in the United States, and the pill forms are considered most effective. They should be taken as early as possible during the typical migraine attack. The most common prophylactic therapies include antidepressants, **beta blockers**, **calcium channel blockers**, and antiseizure medications. Antiseizure medications have proven particularly effective at blocking the actions of neurotransmitters that start migraine attacks. Topiramate (Topamax) was shown effective in several combined clinical trials in 2004 at 50–200 mg per day.

In 2004, a new, large study added evidence to show the effectiveness of botulinum toxin type A (Botox) treatment to prevent headache pain for those with frequent, untreatable tension and migraine headaches. Patients were treated every three months, with two to five injections each time. They typically received relief within two to three weeks.

Cluster headaches may also be treated with ergotamine and sumatriptan, as well as by inhaling pure oxygen. Prophylactic treatments include prednisone, **calcium** channel blockers, and methysergide.

Alternatives

Alternative headache treatments include:

- acupuncture or acupressure
- biofeedback
- chiropractic
- herbal remedies using feverfew (*Chrysanthemum parthenium*), valerian (*Valeriana officinalis*), white willow (*Salix alba*), or skullcap (*Scutellaria lateriflora*), among others
- homeopathic remedies chosen specifically for the individual and his/her type of headache
- hydrotherapy
- massage
- magnesium supplements
- regular physical exercise
- relaxation techniques, such as meditation and yoga
- transcutaneous electrical nerve stimulation (TENS) (A procedure that electrically stimulates nerves and blocks the signals of pain transmission.)

Prognosis

Headaches are typically resolved through the use of **analgesics** and other treatments. Research has shown that people who have migraine headaches more often than once a month may be at increased risk for **stroke**.

Prevention

Some headaches may be prevented by avoiding triggering substances and situations, or by employing alternative therapies, such as **yoga** and regular **exercise**. Since **food allergies** often are linked with headaches, especially cluster headaches, identification and elimination of the allergy-causing food(s) from the diet can be an important preventive measure.

Health care proxy

Definition

A health care proxy, or health care proxy form, is a legal document that allows a person to choose someone to make medical decisions on their behalf when they are unable to do so. In some states the person who is authorized may be called a proxy, in others the person may be called an agent.

Description

A health care proxy form is part of a set of legal documents that allows a person to appoint someone to make medical decisions for them if they cannot act on their own behalf, and to make sure that health care professionals follow their wishes regarding specific medical treatments at the end of life. These documents are referred to as advance directives. The document naming the person appointed to make the decisions is called a health care proxy. The document that lists acceptable and unacceptable measures of artificial **life support** is called a living will. Most states have passed laws that authorize people to draw up living wills, but it is important to get specific information about the laws in the person's own state.

Any competent adult can appoint a health care proxy or agent. It is not necessary to hire a lawyer to draw up or validate the form. Most states, however, require two adult witnesses to sign a proxy form. Many hospitals provide proxy forms on request.

It is important to have a health care proxy in order to be able to choose the person who will be making medical decisions on the patient's behalf. In addition to naming the specific person who will make those decisions, one should think about what life-sustaining treatments one would be willing to undergo in the event of a medical emergency or terminal illness.

A health care proxy form does not deprive a person of the right to make decisions about medical treatment as long as he or she is able to do so. It is put into effect only when the patient's health care team determines that the patient is unable to make decisions on his or her own. For example, a person may be in a **coma** following an automobile accident. The physician would document in the patient's medical record that the patient is unable to make his or her own medical decisions, the circumstances that led to the patient's present condition, the nature of the disease or injury, and the expected length of the patient's incapacitation.

The person named as proxy makes health care decisions only as long as the patient is unable to make them for him- or herself. If the person regains the ability to make his or her own decisions, the proxy will no longer make them. If the incapacitation is permanent, the proxy will continue to make health care decisions on the patient's behalf as long as the patient is alive, or until the proxy is no longer able to carry out the responsibility.

Any trusted adult can be named as a health care proxy. Most married people name their spouse, but it is not necessary to do so. In addition, it is important to select an alternate proxy, in the event that the person first named is unable to fulfill the responsibility. For example, if the spouse has been named as proxy, and both members of the couple were incapacitated in a house fire, then someone else should be empowered to act on their behalf. A married couple does not need to name the same individual as a proxy or as the alternate. It is best to choose someone who lives close enough to carry out the responsibilities of a proxy without having to travel across state lines.

One should consider whether a potential proxy will be able to ask the necessary questions of medical personnel in order to obtain information needed to make a decision. It is important to discuss with the proxy his or her own value system, and whether he or she could make a decision for someone else that he or she would not make for him or herself. It is a good idea to carry the name and contact information of the proxy in one's wallet in the event of an emergency or sudden incapacitation.

The purpose of a living will is to give specific instructions about emergency or end-of-life health care. In some states a living will may be part of the health care proxy document. But because it is impossible to plan for all possible situations, the health care proxy can interpret the patient's wishes to members of the health care team and make decisions that one could not foresee at the time of making a living will. This is why it is important for the proxy to understand

KEY TERMS

Advance directive—A general term for two types of documents, living wills and medical powers of attorney, that allow people to give instructions about health care in the event that they cannot speak for themselves.

Proxy—A person authorized or empowered to act on behalf of another; also, the document or written authorization appointing that person.

the patient's value system, so that the proxy can use his or her judgment as to what one would want. The proxy should be given a written copy of all advance directives.

Even if a living will is not legal in the state in which one resides, writing such a will is an opportunity to think through personal beliefs and health care preferences. The proxy or agent can then can use the living will as a guide in making health care decisions as need arises. Some areas to consider are:

- What makes my life meaningful?
- What religious or personal beliefs do I hold that affect my health care decisions?
- Do I want my proxy to make health care decisions on his or her own, or are there other people I would want him or her to consult? If so, who are these people? Is there anyone who should not be consulted?
- Who besides myself will be affected by these decisions? Are they aware of my value system? Would they try to interfere with the proxy's decisions?
- What do I want to do about organ donation?
- Have I informed my physician of my wishes?

Appointing a health care proxy is not an irrevocable decision. One can change or revoke the proxy at any time, usually by filling out a new form. In some states, one can specify that the health care proxy will expire on a certain date or if certain events occur. If a person has named his or her spouse as an agent, the proxy is no longer in effect in the event of separation or divorce. People who want a former spouse to continue as their agent must complete a new proxy form.

In addition to keeping a copy of the proxy form in a person file of important documents, the person should give copies to the proxy, the alternate, and his or her physicians.

Health history

Definition

The health history is a current collection of organized information unique to an individual. Relevant aspects of the history include biographical, demographic, physical, mental, emotional, sociocultural, sexual, and spiritual data.

Purpose

The health history aids both individuals and health care providers by supplying essential information that will assist with diagnosis, treatment decisions, and establishment of trust and rapport between lay persons and medical professionals. The information also helps determine an individual's baseline, or what is normal and expected for that person.

Every person should have a thorough health history recorded as a component of a periodic **physical examination**. These occur frequently (monthly at first) in infants and gradually reach a frequency of once per year for adolescents and adults.

Description

The clinical interview is the most common method for obtaining a health history. When a person or a designated representative can communicate effectively, the clinical interview is a valuable means for obtaining information.

The information that comprises the health history may be obtained from a person's previous records, the individual, or in some cases, significant others or caretakers. The depth and length of the history-taking process is affected by factors such as the purpose of the visit, the urgency of the complaint or condition, the person's willingness or ability to contribute information, and the environment in which information is sought. When circumstances allow, a history may be holistic and comprehensive, but at times only a cursory review of the most pertinent facts is possible. In cases where the history-gathering process needs to be abbreviated, the history focuses on a person's medical experiences.

Health histories can be organized in a variety of ways. Often a hospital or clinic will provide a form, template, or computer database that serves as a guide and documentation tool for the history. Generally, the first aspect covered by the history is identifying data.

Identifying or basic demographic data includes facts such as:

- name
- gender
- age
- date of birth
- occupation
- family structure or living arrangements
- source of referral

Once the basic identifying data is collected, the history addresses the reason for the current visit in expanded detail. The reason for the visit is sometimes referred to as the chief complaint or the presenting complaint. Once the reason for the visit is established, additional data are solicited by asking for details that provide a more complete picture of the current clinical situation. For example, in the case of **pain**, aspects such as location, duration, intensity, precipitating factors, aggravating factors, relieving factors, and associated symptoms should be recorded. The full picture or story that accompanies the chief complaint is often referred to as the history of present illness (HPI).

The review of systems is a useful method for gathering medical information in an orderly fashion. This review is a series of questions about the person's current and past medical experiences. It usually proceeds from general to specific information. A thorough record of relevant dates is important in determining relevance of past illnesses or events to the current condition. A review of systems typically follows a head-to-toe order.

The names for categories in the review of systems may vary, but generally consists of variations on the following list:

- head, eyes, ears, nose, throat (HEENT)
- cardiovascular
- respiratory
- gastrointestinal
- genitourinary
- integumentary (skin, hair, and nails)
- musculoskeletal, including joints
- endocrine
- nervous system, including both central and peripheral components
- mental, including psychiatric issues

KEY TERMS

Holistic—Pertaining to all aspects of the patient, including biological, psychosocial, and cultural factors.

Subjective—Influenced by the perspective of the information provider; potentially biased.

Past and current medical history includes details on medicines taken by the person, as well as **allergies**, illnesses, hospitalizations, procedures, pregnancies, environmental factors such as exposure to chemicals, toxins, or **carcinogens**, and health maintenance habits such as breast or **testicular self-examination** or immunizations.

An example of a series of questions might include the following:

- How are your ears?
- Are you having any trouble hearing?
- Have you ever had any trouble with your ears or with your hearing?

If an individual indicates a history of auditory difficulties, this would prompt further questions about medicines, surgeries, procedures, or associated problems related to the current or past condition.

In addition to identifying data, chief complaint, and review of systems, a comprehensive health history also includes factors such as a person's family and social life, family medical history, mental or emotional illnesses or stressors, detrimental or beneficial habits such as **smoking** or **exercise**, and aspects of culture, sexuality, and spirituality that are relevant to each individual. The clinicians also tailor their interviewing style to the age, culture, educational level, and attitudes of the persons being interviewed.

Precautions

The information obtained from the interview is subjective; therefore, it is important that the interviewer assess the person's level of understanding, education, communication skills, potential biases, or other information that may affect accurate communication. Thorough training and practice in techniques of interviewing such as asking open-ended questions, listening effectively, and approaching sensitive topics such as substance **abuse**, chemical dependency, domestic violence, or sexual practices assists a clinician in obtaining the maximum amount of information without upsetting the person being questioned or disrupting the interview. The interview should be preceded by a review of the chart and an introduction by the clinician. The health care professional should explain the scope and purpose of the interview and provide privacy for the person being interviewed. Others should only be present with the person's consent.

Aftercare

Once a health history has been completed, the person being queried and the examiner should review the relevant findings. A health professional should discuss any recommendations for treatment or follow-up visits. Suggestions or special instructions should be put in writing. This is also an opportunity for persons to ask any remaining questions about their own health concerns.

Health care team roles

A health history is best obtained by a physician who has the training to appreciate nuances and details that may be overlooked by those with less training. Other health care professionals such as physician assistants and nurse practitioners have similar but somewhat limited training. Health histories are usually obtained in professional offices or hospitals. Occasionally, they are obtained in private homes or in the field.

Hearing aids

Definition

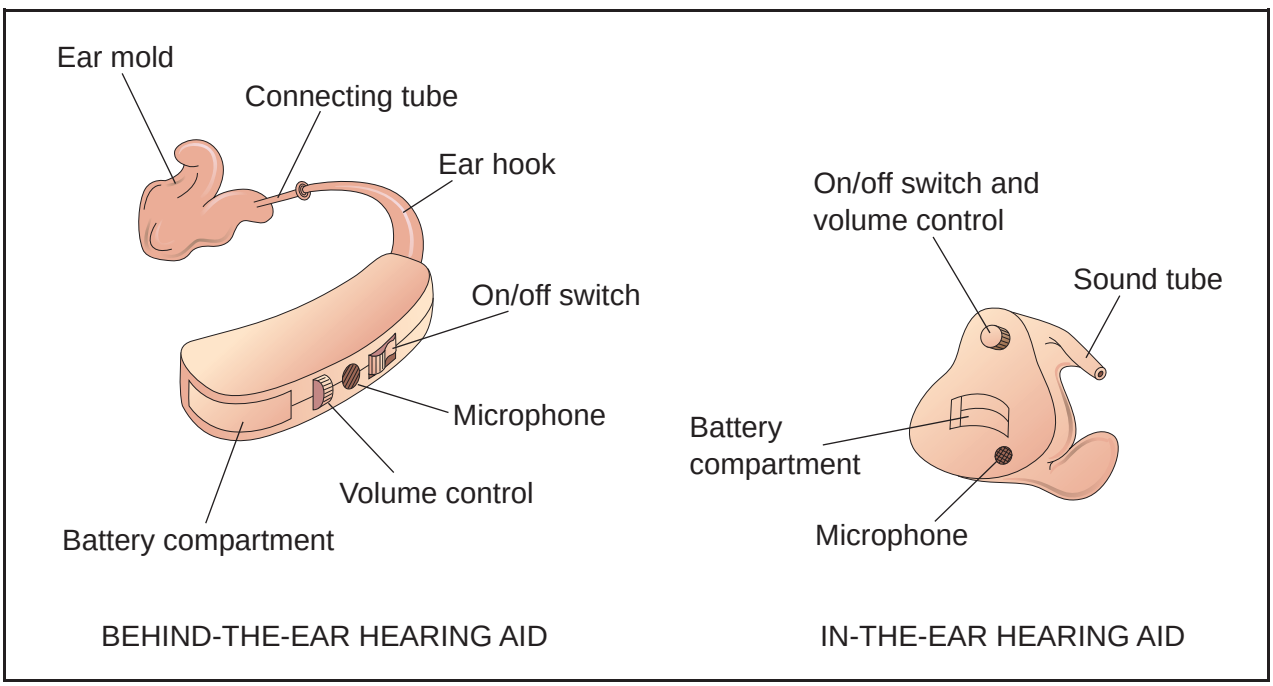
A hearing aid is a device that can amplify sound waves in order to help a deaf or hard-of-hearing person hear sounds more clearly.

Purpose

Recent technology can help most people with **hearing loss** understand speech better and achieve better communication.

Precautions

It is important that a person being fitted for a hearing aid understand what an aid can and cannot do. An aid can help a person hear better, but it will not return hearing to normal levels. Hearing aids boost all sounds, not just those the person wishes to hear. Especially when the source of sound is far away (such as up on a stage), environmental noise can interfere with good speech perception. In addition, while the aid amplifies sound, it does not necessarily improve the clarity of the sound. A hearing aid is a machine and can never duplicate the true sound that people with normal hearing experience, but it will help the person take advantage of the hearing that remains.



Hearing aids are devices that can amplify sound waves to help a deaf or hard-of-hearing person hear sounds more clearly. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Description

More than 1,000 different models are available in the United States. All of them include a microphone (to pick up sound), amplifier (to boost sound strength), a receiver or speaker (to deliver sound to the ear), and are powered by a battery. Depending on the style, it is possible to add features to filter or block out background noise, minimize feedback, lower sound in noisy settings, or boost power when needed.

Hearing aids are either "monaural" (a hearing aid for one ear), or "binaural" (for two ears); more than 65% of all users have binaural aids. Hearing aids are divided into several different types:

- digital
- in-the-ear
- in-the-canal
- behind-the-ear
- on-the-body

Digital aids are sophisticated, very expensive aids that borrow computer technology to allow a person to tailor an aid to a specific hearing loss pattern. Using miniature computer chips, the aids can selectively boost certain frequencies while leaving others alone. This means a person could wear such an aid to a loud party and screen out unwanted background noise, while tuning in on one-on-one conversations. The aid is programmed by the dealer to conform to the patient's specific hearing loss. Some models can be programmed to allow the wearer to choose different settings depending on the noise of the environment.

In-the-ear aids are lightweight devices whose custom-made housings contain all the components; this device fits into the ear canal with no visible wires or tubes. It's possible to control tone but not volume with these aids, so they are helpful only for people with mild hearing loss. Some people find these aids are easier to put on and take off than behind-the-ear aids. However, because they are custom-fit to a person's ear, it is not possible to try on before ordering. Some people find them uncomfortable in hot weather.

In-the-canal aids fit far into the ear canal, with only a small bit extending into the external ear. The smallest is the MicroCanal, which fits out of sight down next to the eardrum and is removed with a small transparent wire. These are extremely expensive, but they are not visible, offer better acoustics, and are easier to maintain. They can more closely mimic natural sound because of the position of the microphone, this position also cuts down on wind noise. However, their small size makes them harder to handle, and their battery is especially small and difficult to insert. Adjusting the volume may be hard, since a person must stick a finger down into the ear to adjust volume, and this very tiny aid does not have the power of other, larger aids.

Behind-the-ear aids include a microphone, amplifier, and receiver inside a small curved case worn behind the ear; the case is connected to the earmold by a short plastic tube. The earmold extends into the ear canal. Some models have both tone and volume control plus a telephone pickup device. Many users think them unattractive and out of date, and people who wear glasses find that the glasses interfere with the aid's fit. Others do not have space behind the ear for the mold to fit comfortably. However, they do offer a few advantages.

Behind-the-ear aids:

- require less maintenance
- are easily interchangeable if they need to be serviced
- are more powerful
- are easier to handle than smaller aids
- can provide better sound quality
- tend to be more reliable

Eyeglass models are the same as behind-the-ear devices, except that the case fits into an eyeglass frame instead of resting behind the ears. Not many people buy this type of aid, but those who do believe it is less obvious, although there is a tube that travels from the temple of the glasses to the earmold. However, it can be hard to fit this type of aid, and repairs can be problematic. Also, if the aid breaks, the person also loses the benefit of the glasses.

CROS or the crossover system type of hearing aid is often used in conjunction with the eyeglass model. The CROS (contralateral routing of signal) system features a microphone behind the ear that feeds the amplified signal to the better ear, eliminating "head shadow," which occurs when the head blocks sound from the better ear. This type may help make speech easier to understand for people with a high-frequency loss in both ears.

A BI-CROS system uses two microphones (one above each ear) that send signals to a single amplifier. Sound then travels to a single receiver, which transfers it to the better ear via a conventional earmold.

On-the-body aids feature a larger microphone, amplifier, and power supply inside a case carried inside the pocket, or attached to clothing. The receiver attaches directly to the earmold; its power comes through a flexible wire from the amplifier. Although larger than other aids, the on-the-body aids are more powerful and easier to adjust than other devices. While

WWW.BOOKBAZ.IR

not popular for everyone, they are often used by those with a profound hearing loss, or by very young children. Some people who are almost totally deaf find they need the extra power boost available only from a body aid.

The latest aids on the market may eliminate the amplifier and speaker in favor of a tiny magnet mounted on a silicone disk, similar to a contact lens, which rests right on the eardrum. Called the Earlens, it is designed to be held in place by a thin film of oil. Users wear a wireless microphone, either in the ear or on a necklace, that picks up sounds and converts them into magnetic signals, making the magnet vibrate. As the Earlens vibrates, so does the eardrum, transmitting normal-sounding tones to the middle and inner ears.

Other researchers are bypassing the middle ear completely; they surgically implant a tiny magnet in the inner ear. By attaching a magnet to the round window, they open a second pathway to the inner ear. An electromagnetic coil implanted in bone behind the ear vibrates the implanted magnet. Unlike the Earlens, this magnetic implant would not block the normal hearing pathway.

Preparation

The fist step in getting a hearing aid is to have a medical exam and a hearing evaluation. (Most states prohibit anyone selling a hearing aid until the patient has been examined by a physician to rule out medical problems.) After performing a hearing evaluation, an audiologist should be able to determine whether a hearing aid will help, and which one will do the most good. This is especially important because aids can be very expensive (between $500 and $4,000) and are often not covered by health insurance. Hearing aids come in a wide range of styles and types, requiring careful testing to make sure the aid is the best choice for a particular hearing loss.

Some audiologists sell aids; others can make a recommendation, or give one a list of competent dealers in one's area. Patients should shop around and compare prices. In all but three states, hearing aids must be fitted and sold only by licensed specialists called dealers, specialists, dispensers, or dispensing audiologists.

The hearing aid dealer will make an impression of the consumer's ears using a putty-like material, from which a personalized earmold will be created. It's the dealer's job to make sure the aid fits properly. The person may need several visits to find the right hearing aid and learn how to use it. The dealer will help the consumer learn how to put the aid on, adjust the controls, and maintain the device. The dealer should be willing to service the aid and provide information about what to do if sensitivity to the earmold develops. (Some people are allergic to the materials in the mold.)

KEY TERMS

Audiologist—A person with a degree and/or certification in the areas of identification and measurement of hearing impairments and rehabilitation of those with hearing problems.

Eardrum—A paper-thin covering stretching across the ear canal that separates the middle and outer ears.

Middle ear—The small cavity between the eardrum and the oval window that houses the three tiny bones of hearing.

Oval window—A tiny opening at the entrance to the inner ear.

Aftercare

Within several weeks, the wearer should return to the dealer to have the aid checked, and to discuss the progress in wearing the aid. About 40% of all aids need some modification or adjustment in the beginning.

Within the first month of getting an aid, the patient should make an appointment for a full hearing examination to determine if the aid is functioning properly.

Risks

While there are no medical risks to hearing aids, there is a risk associated with hearing aids: many people end up not wearing their aids because they say everything seems loud when wearing them. This is because they have lived for so long with a hearing problem that they have forgotten how loud "normal" sound can be. Other potential problems with hearing aids include earmold discomfort and a build up of excess ear wax after getting a hearing aid.

Results

A hearing aid will boost the loudness of sound, which can improve a person's ability to understand speech.

Carol A. Turkington

Hearing loss

Definition

Hearing loss is any degree of impairment of the ability to apprehend sound. Such impairment occurs primarily due to natural causes (heredity) and environmental factors (extended exposure to loud sounds). Secondary factors of hearing loss include obstructions within the ear canal, primarily ear wax but sometimes also other natural or foreign materials.

Decibel ratings and hazardous levels of noise

Decibel level	Examples of sounds
30	Soft whisper
35	Noise may prevent listener from falling asleep
40	Quiet office noise level
50	Quiet conversation
60	Average television volume, sewing machine, lively conversation
70	Busy traffic, noisy restaurant
80	Heavy city traffic, factory noise, alarm clock
90	Cocktail party, lawn mower
100	Pneumatic drill
120	Sandblasting, thunder
140	Jet airplane
180	Rocket launching pad

At volumes above 110 decibels, hearing may become painful.
A volume above 120 decibels is considered deafening.
At volumes above 135 decibels, hearing will become extremely painful and hearing loss may result if exposure is prolonged.
At volumes above 180 decibels, hearing loss is almost certain with any exposure.

(Table by PreMediaGlobal. © Cengage Learning®.)

Demographics

Generally, some hearing loss occurs gradually as humans get older. According to the National Institutes of Health, about one out of three older Americans between the ages of 65 and 75 years has hearing loss. Over the age of 75 years, hearing loss occurs in about one out two people in the United States. However, hearing loss can happen to any person regardless of age.

Description

Sound can be measured accurately. The term decibel (dB) refers to an amount of energy moving sound from its source to one's ears or to a microphone. For instance, a whisper is equivalent to about 30 dB and a washing machine is around 70 dB, both well within the range that will not produce hearing loss. However, heavy traffic and a hair dryer each produce about 85–90 dB, which is within the range that is considered risky for producing a loss of hearing. Even worse, a jet taking off and a shotgun blast each produce between 140 and 165 dB, which is within the range that can cause considerable degradation to one's hearing. In fact, a drop of more than 10 dB in the level of sound a person can hear is significant.

Sound travels through a medium like air or water as waves of compression and rarefaction. These waves are collected by the external ear and cause the tympanic membrane (ear drum) to vibrate. The chain of ossicles connected to the ear drum—the incus, malleus, and stapes—carry the vibration to the oval window, increasing its amplitude 20 times on the way. There the energy causes a standing wave in the watery liquid (endolymph) inside the Organ of Corti. (A standing wave is one that does not move. A vibrating cup of coffee, for instance, will demonstrate standing waves.) The configuration of the standing wave is determined by the frequency of the sound. Many thousands of tiny nerve fibers detect the highs and lows of the standing wave and transmit their findings to the brain, which interprets the signals as sound.

To summarize, sound energy passes through the air of the external ear, the bones of the middle ear and the liquid of the inner ear. It is then translated into nerve impulses, sent to the brain through nerves and understood there as sound. It follows that there are five steps in the hearing process:

- air conduction through the external ear to the ear drum

WWW.BOOKBAZ.IR

An Oto-Acoustic Emission (OAE) hearing test being performed on a newborn baby. The probe emits harmless sound into the baby's ear, and the response of the inner ear is detected and registered on a computer. Early diagnosis of a hearing disorder is important in young children, who may experience difficulties in speech and language development. *(James King-Holmes/Photo Researchers, Inc.)*

- bone conduction through the middle ear to the inner ear
- water conduction to the Organ of Corti
- nerve conduction into the brain
- interpretation by the brain.

Hearing can be interrupted (that is, hearing loss can result) in several ways at each of the five steps.

Risk factors

Some of the risk factors that can lead to hearing loss include:

- Age: Exposure to loud sounds over many years
- Heredity: Being born within a family that is prone to hearing loss
- Occupation: A person's place of work or employment—one that involves loud noises on a regular basis (such as construction workers using pneumatic hammers or loggers using chain saws)
- Recreation: Exposure to loud noises during recreational activities, such as rock concerts, snowmobiling, and automobile races, along with the use of musical and other sound-generating devices hooked up directly to the ear
- Illnesses: Medical conditions that involve exceptionally high fevers, such as meningitis
- Medications: Continual use of drugs, such as pain relievers and nonsteroidal anti-inflammatory drugs

Causes and symptoms

The external ear canal can be blocked with ear wax, **foreign objects**, infection, and tumors. Wax build-up can cause hearing loss in people of any age. Overgrowth of the bone, a condition that occurs when the ear canal has been flushed with cold water repeatedly for years, can also narrow the passageway, making blockage and infection more likely. This condition occurs often in Northern Californian surfers and is therefore called "surfer's ear."

The ear drum is so thin a physician can see through it into the middle ear. Sharp objects, pressure from an infection in the middle ear, or even a firm cuffing or slapping of the ear, can rupture it. It is also susceptible to pressure changes during scuba diving.

Several conditions can diminish the mobility of the ossicles (small bones) in the middle ear. **Otitis media** (an infection in the middle ear) occurs when fluid cannot escape into the throat because of blockage of the eustachian tube. The fluid then accumulates—whether it is pus or just mucus—which dampens the motion of the ossicles. A disease called **otosclerosis** can bind the stapes in the oval window and thereby cause deafness.

All of the conditions mentioned so far that occur in the external and middle ear are causes of conductive hearing loss.

The second category, sensory hearing loss, refers to damage to the Organ of Corti and the acoustic nerve. Prolonged exposure to loud noise is the leading cause of sensory hearing loss. At least one million people have this condition in the United States, many of whom were identified during the military draft and rejected as being unfit for duty. The cause is often believed to be prolonged exposure to rock music. Occupational noise exposure is the other leading cause of noise induced hearing loss (NIHL) and is ample reason for wearing ear protection on the job. A third of people over 65 years of age have presbycusis—sensory hearing loss due to **aging**. Both NIHL and presbycusis are primarily high frequency losses. In most languages, the high frequency sounds define speech, so these people hear plenty of noise. They just cannot easily make out what it means. They have particular trouble selecting out speech from background noise.

Brain infections like **meningitis**, drugs such as the aminoglycoside **antibiotics** (streptomycin, gentamycin, kanamycin, tobramycin), and Meniere's disease also cause permanent sensory hearing loss. Meniere's disease combines attacks of hearing loss with attacks of vertigo. The symptoms may occur together or separately. High doses of salicylates like **aspirin** and quinine can cause a temporary high-frequency loss. Prolonged high doses can lead to permanent deafness. There is an hereditary form of sensory deafness and a congenital form most often caused by **rubella** (German **measles**).

The general symptoms of hearing loss include the following:

- Unclear (muffled) voices and noises
- Difficulty with the understanding of spoken words, especially when background noises are present
- Requests for people to talk slowly or more distinctly
- Inability to participate in conversations
- Reluctance to attend social events

Sudden hearing loss—at least 30dB in less than three days—is most commonly caused by cochleitis, a mysterious viral infection.

The final category of hearing loss is neural. Damage to the acoustic nerve and the parts of the brain that perform hearing are the most likely to produce permanent hearing loss. Strokes, **multiple sclerosis**, and acoustic neuromas are all possible causes of neural hearing loss.

Hearing can also be diminished by extra sounds generated by the ear, most of them from the same kinds of disorders that cause diminished hearing. These sounds are referred to as **tinnitus** and can be ringing, blowing, clicking, or anything else that no one but the patient hears.

Diagnosis

An examination of the ears and nose combined with simple hearing tests done in the physician's office can detect many common causes of hearing loss. An audiogram often concludes the evaluation, since this simple means often produces a diagnosis. If the defect is in the brain or the acoustic nerve, further neurological testing and imaging will be required.

The audiogram has many uses in diagnosing hearing deficits. The pattern of hearing loss across the audible frequencies gives clues to the cause. Several alterations in the testing procedure can give additional information. For example, speech is perceived differently than pure tones. Adequate perception of sound combined with inability to recognize words points to a brain problem rather than a sensory or conductive deficit. Loudness perception is distorted by disease in certain areas but not in others. Acoustic neuromas often distort the perception of loudness.

Treatment

Conductive hearing loss can almost always be restored to some degree, if not completely. Some ways to restore hearing loss are:

- matter in the ear canal can be easily removed with a dramatic improvement in hearing.
- surfer's ear gradually regresses if cold water is avoided or a special ear plug is used. In advanced cases, surgeons can grind away the excess bone.
- middle ear infection with fluid is also simple to treat. If medications do not work, surgical drainage of the ear is accomplished through the ear drum, which heals completely after treatment.
- traumatically damaged ear drums can be repaired with a tiny skin graft.

WWW.BOOKBAZ.IR

- surgical repair of otosclerosis through an operating microscope is one of the most intricate of procedures, substituting tiny artificial parts for the original ossicles.

Sensory and neural hearing loss, on the other hand, cannot readily be cured. Fortunately, the loss is not often complete, so that **hearing aids** can fill the deficit.

In-the-ear hearing aids can boost the volume of sound by up to 70 dB. (Normal speech is about 60 dB.) Federal law now requires that they be dispensed only with a physician's prescription. For complete conduction hearing loss there are now available bone conduction hearing aids and even devices that can be surgically implanted in the cochlea.

Tinnitus can sometimes be relieved by adding white noise (like the sound of wind or waves crashing on the shore) to the environment.

Decreased hearing is such a common problem that there are legions of organizations to provide assistance. Special language training, both in lip reading and signing, special schools, and special camps for children are all available in most regions of the United States.

Alternatives

Conductive hearing loss can be treated with alternative therapies that are specific to the particular condition. Sensory hearing loss may be helped by homeopathic therapies. Oral supplementation with essential fatty acids such as flax oil and omega 3 oil can help alleviate the accumulation of wax in the ear.

Prognosis

The prognosis for reducing or eliminating hearing loss widely varies. Whether hearing loss can be solved is generally dependent on the cause. Conductive hearing loss is usually able to be cured. However, sensory hearing loss is more complicated to treat and is usually not curable. People can regain a majority of their hearing with the use of hearing aids.

Prevention

Prompt treatment and attentive follow-up of middle ear infections in children will prevent this cause of conductive hearing loss. Control of infectious childhood diseases, such as measles, has greatly reduced sensory hearing loss as a complication of epidemic diseases. Laws that require protection from loud noise in the workplace have achieved substantial reduction in noise induced hearing loss. Surfers should use the right kind of ear plugs.

KEY TERMS

Decibel—A unit of the intensity of sound, a measure of loudness.

Meniere's disease—The combination of vertigo and decreased hearing caused by abnormalities in the inner ear.

Multiple sclerosis—A progressive disease of brain and nerve tissue.

Otosclerosis—A disease that scars and limits the motion of the small conducting bones in the middle ear.

Stroke—Sudden loss of blood supply to part of the brain.

Heart attack

Definition

A heart attack is the death of, or damage to, heart muscle because the supply of blood to the heart is severely restricted or blocked. It occurs usually when a blood clot prevents the flow of blood through a coronary artery, which provides blood to the heart muscle. Heart attacks, also called myocardial infarctions (MIs), can be fatal although improvements in treatment immediately after a heart attack have reduced the number of deaths.

Description

A heart attack occurs when one or more of the coronary arteries that supply blood to the heart are completely or substantially blocked and not enough oxygen reaches the heart (a condition called ischemia). The blockage usually is caused by atherosclerosis, the build-up of plaque in the artery walls, and/or by a blood clot in a coronary artery. Much less often, a healthy coronary artery has a spasm, and blood flow to part of the heart suddenly decreases or stops. Coronary artery spasm in young, healthy individuals is most often brought on by **methamphetamine** or cocaine use.

A heart attack is medically distinct from sudden cardiac arrest, which is a condition in which the heart abruptly stops functioning. Sudden cardiac arrest occurs when an electrical disturbance in the heart disturbs its pumping action of blood throughout the body. The condition of cardiac arrest can be caused by a heart attack, but other causes are also possible.

About half of all people who have heart attacks wait at least two hours before seeking help. Waiting increases their chance of death or becoming permanently disabled. The longer an artery remains blocked during a heart attack, the more damage is done to the heart. Therefore, it is important to recognize the signs of a heart attack and seek prompt medical attention at the nearest hospital with 24-hour emergency cardiac care.

About one-fifth of all heart attacks are silent; that is, the individual does not know one has occurred. Although the person feels no **pain**, silent heart attacks still damage the heart.

The outcome of a heart attack depends on where the blockage is, whether heart rhythm is disturbed, and whether another coronary artery supplies blood to that part of the heart. Blockages in the left coronary artery usually are more serious than in the right coronary artery. Blockages that cause an arrhythmia, an irregular heartbeat, can cause sudden death.

Major risk factors

Major risk factors significantly increase the risk of **coronary artery disease**. Those that cannot be changed include:

- Heredity. People whose parents have coronary artery disease are more likely to develop it. The risk of heart attack is highest for those who have a male parent or sibling who has had a heart attack before the age of 45 years or a female parent or sibling who has had a heart attack before age 55.
- Gender. Men under 60 years of age are more likely to have heart attacks than are women of the same age.
- Age. Men over the age of 45 years and women over the age of 55 are considered at risk for having a heart attack. Older people (those over 65) are at increased risk of dying from a heart attack. Older women are twice as likely to die within a few weeks of a heart attack as are men of the same age.

Major risk factors that can be modified through lifestyle changes include:

- Using tobacco. Smoking, chewing, and other ways of using tobacco products greatly increases both the chance of developing coronary artery disease and the change of dying from it. Smokers are more than twice as likely to have a heart attack and have two to four times the risk of nonsmokers of sudden cardiac death. They also are more likely to die within an hour of a heart attack. Exposure to second-hand smoke

WWW.BOOKBAZ.IR

(being in close proximity to someone who smokes) and third-hand smoke (coming into close and long-term contact with materials that contain tobacco smoke, such as carpet) also increases risk.

- High cholesterol levels. Cholesterol is a soft, waxy substance that is produced by the liver. It is also obtained from eating cholesterol-containing food, such as meat, eggs, and other animal products. Cholesterol level is affected by age, sex, heredity, and diet. For instance, being obese (extremely overweight) with high cholesterol increases one's risk even more for a heart attack. Cholesterol does not dissolve in blood. Instead, it moves through the circulatory system in combination with carrier substances called lipoproteins. There are two types of carrier-cholesterol combinations, low-density lipoprotein (LDL) or so-called bad cholesterol and high-density lipoprotein (HDL) or so-called good cholesterol. LDL picks up cholesterol in the liver and carries it through the circulatory system. Most of the cholesterol in the body is LDL cholesterol. When too much LDL cholesterol is present, it begins to drop out of the blood and stick to the walls of the arteries. The sticky material on the artery walls is called cholesterol plaque. Plaque can reduce the amount of blood flowing through the arteries and encourage blood clots to form. Total cholesterol of 240 milligrams per deciliter (mg/dL) and over poses a high risk, and from 200 mg/dL to 239 mg/dL, a borderline high risk. For LDL cholesterol, high risk ranges from 130 mg/dL to 159 mg/dL, depending on other risk factors. Researchers contend that HDL works opposite LDL. HDL picks cholesterol off the walls of the arteries and takes it back to the liver where it can be broken down and removed from the body. This helps to keep the blood vessels open. Cholesterol can be measured by a simple blood test. To reduce the risk of cardiovascular disease, adults should keep their HDL cholesterol above 40 mg/dL.
- High triglyceride levels. A type of blood fat, triglyceride (also called triacylglycerol or triacylglyceride), also contributes to an increased risk of atherosclerosis and, consequently, for heart attack or stroke. Triglyceride is an ester that originates from glycerol and three fatty acids. They are the main component of animal fats (saturated fats) and vegetable oils (unsaturated fats).
- High blood pressure (hypertension). High blood pressure makes the heart work harder and over time weakens it. It increases the risk of heart attack, stroke, kidney failure, and congestive heart failure. A blood pressure of 140 millimeters of mercury (mm Hg) over 90 mm Hg (commonly abbreviated 140 over 90) or above is considered high. As the numbers increase, high blood pressure goes from being categorized as Stage 1 (mild) to Stage 4 (very severe). African Americans are at increased risk of developing severe hypertension.
- Obesity and lack of physical activity. The heart of an obese individual must work harder, while lack of physical activity (inactive lifestyle) increases the risk of coronary artery disease. Even modest physical activity, especially aerobic exercise, is beneficial if done regularly.
- Use of certain drugs or supplements. In the late twentieth century, ephedra (ma huang) gained popularity as a weight-loss supplement. The herb can cause life-threatening side effects, including heart attack, stroke, and seizures. Since April 2004, sale of products containing ephedra were banned in the United States, although it could still be obtained illegally over the Internet. Hormone replacement therapy (HRT) was once thought to help prevent heart disease in postmenopausal women. However, the Women's Health Initiative, a very large clinical trial, found the opposite to be true. Potential adverse effects of HRT include increased risk of heart attack, stroke and blood clots, and an increased risk of breast cancer. Illegal drugs such as stimulant drugs (cocaine and amphetamines, for example) can make arteries spasm into a heart attack.

Contributing risk factors

Contributing risk factors have been linked to coronary artery disease, but their significance or prevalence cannot always be demonstrated or quantified. Contributing risk factors include:

- Diabetes mellitus. The risk of developing coronary artery disease is seriously increased for individuals with uncontrolled diabetes or the body's inability to produce sufficient amounts of insulin or to respond properly to insulin production. More than 80% of diabetics die of some type of heart or blood vessel disease.
- Emotional factors. Long-term stress, anger, and guilt are thought to contribute to the development of coronary artery disease. Stress, the mental and physical reaction to life's problemss and challenges, increases the heart rate and blood pressure and can injure the lining of the arteries. Evidence shows that anger increases the risk of dying from heart disease and more than doubles the risk of having a heart attack right after an episode of anger.
- History of preeclampsia in women. During pregnancy, women who have high blood pressure (along

with high concentration of protein in the urine after the 20th week of pregnancy) have an increased risk for heart disease and heart attack over a lifetime.

Demographics

Heart attack is the leading cause of death in the United States. More than 1.5 million Americans experience a heart attack every year, and between 500,000 and 700,000 of them die. Nearly, half of these people did not experience any prior symptoms or have any warning signs before their heart attack. As of 2013, about 7.9 million Americans have had a heart attack but are still living.

About 435,000 women in the United States have a heart attack annually, with 83,000 of them under the age of 65 years and 35,000 of them under the age of 55. About 267,000 women die each year from heart attacks. Further, about 42% of women who have heart attacks die within the first year, while only 24% of men die during this same period. Thus, women are about twice as likely to die from a heart attack as are men when under the age of 50 years.

Internationally, the World Health Organization (WHO) states that cardiovascular diseases (CVDs) kills about 17.3 million people each year, mostly from heart attacks and strokes. Of that number, 4.7 million die in the Western Pacific, 3.6 million in South-East Asia; 4.6 million in Europe, 1.9 million in the Americas, 1.3 million in Africa, and 1.2 million in the East Mediterranean.

Most heart attacks are the result of years of silent but progressive coronary artery disease (CAD); a heart attack may be the first symptom of the disease. According to the American Heart Association, 63% of women and 48% of men who died suddenly of coronary artery disease had no previous symptoms.

Causes and symptoms

Heart attacks generally are the result of severe coronary artery disease. Most heart attacks are caused by **blood clots** that form on atherosclerotic plaque. This buildup of **cholesterol** and other fatty substances, what is generally called plaque, forms over time on the interior walls of coronary arteries, those arteries that contain oxygen-rich blood to the heart. When plaque forms on arteries, the arteries become narrowed, causing the medical condition known as coronary artery disease. These clots may break loose and travel through the circulatory system causing heart attack or **stroke** (blockage of an artery to the brain).

Another cause of heart attacks is a spasm of a coronary artery, which stops blood flow to a part of the heart muscle. Still another cause is a condition called spontaneous coronary artery dissection or a tear in a heart artery. Causes of heart attacks that do not occur very frequently include small blood clots that move to the heart from other locations within the circulatory system of the body, and circumstances that cause very low blood pressure, such as when the body goes into **shock** from a medical condition or a serious accident.

Certain major risk factors increase the chance of developing coronary artery disease. Some of these can be modified and some cannot. People with a greater number of risk factors are more likely to develop coronary artery disease.

Symptoms, or the lack of symptoms, vary from person to person when having a heart attack. The intensity of those symptoms also varies widely between individuals. A majority of people—over 60%—who have had a heart attack experience symptoms before the heart attack occurs. These symptoms sometimes occur days or weeks before the heart attack. For instance, some people have repeat chest pain (called **angina**) that comes and goes, often times getting worse with exertion and becoming less noticeable or even going away totally when resting. Sometimes, people do not recognize the symptoms of a heart attack or are in denial that they are having one. Typical symptoms include:

- Uncomfortable pressure, fullness or tightness, squeezing, or aching pain in the center of the chest (angina) that lasts more than 30 minutes. Warning pains before a heart attack may last a shorter time or may go away with rest and then return.
- Pain that spreads to the shoulders, neck, arms, or jaw
- Feeling of abdominal pain, heartburn, fullness, or indigestion
- Shortness of breath
- Sweating or a cold sweat
- Feelings of fatigue
- Sleeplessness
- Feelings of anxiety or an impending sensation of doom (such as death or calamity)
- Lightheadedness or dizziness, fainting, or nausea

All of these symptoms do not occur with every heart attack, and most have other common causes. Nevertheless, a person with any of these symptoms should immediately call an emergency rescue service (recommended) or be driven (but not drive themselves) to the nearest hospital with a 24-hour cardiac

WWW.BOOKBAZ.IR

care unit. The advantage of calling an emergency rescue service is that life-saving treatment may begin while the individual is in transit to the hospital.

Diagnosis

Experienced emergency care personnel usually can diagnose a heart attack simply by looking at the patient. However, medical tests can be extremely helpful when confirming that someone has had a heart attack.

Tests

To confirm this diagnosis, the medical professional will talk with the patient, check heart rate and blood pressure, perform an electrocardiogram, and take a blood sample. The electrocardiogram shows whether damage has occurred to the heart. Electrodes covered with conducting jelly are placed on the patient's chest, arms, and legs. They send impulses of the heart's electrical activity through an oscilloscope (a monitor) to a recorder, which traces them on paper. Damaged hearts produce a different electrical pattern from healthy hearts. The blood test shows the leak of cardiac enzymes or other biochemical markers from damaged cells in the bloodstream.

Other tests include a chest x ray to determine the size of the heart and its blood vessels and to inspect the lungs for any fluid built up in them. An angiogram, or coronary catheterization, is performed to see if the coronary arteries are narrowed or blocked. Liquid dye is injected into the arteries of the heart so they are visible on x-ray scans as being blocked or not. While the angiogram is being performed and the results show blockage of an artery or more than one artery, the attending surgeon may perform an **angioplasty**. It is also called a coronary artery balloon dilation, balloon angioplasty, or percutaneous coronary intervention. The procedure uses tiny balloons to widen the blocked areas of the arteries. A stent (mesh tube) may also be placed inside the artery to keep it from narrowing again.

Cardiac computerized tomography (CT) scans or **magnetic resonance imaging** (MRI) scans may also be used to diagnose problems with the heart. With CT, x-ray images are taken at various angles of the heart so a complete image can be developed of the heart and chest. With MRI, a magnetic field aligns atomic particles of the cells with the field of view so images can be produced of the different types of cells.

Treatment

The goal of treatment is to restore adequate blood flow and oxygen delivery to the heart, relieve pain, and prevent complications. Heart attacks are treated with **cardiopulmonary resuscitation** (CPR) when necessary to start and keep the patient breathing and the heart beating. Beta-blocker drugs may be given to help control heart rate. Other drugs may be used to relieve pain and **anxiety**. These treatments may be started by trained emergency medical service personnel in the ambulance on the way to the hospital.

Traditional

Once at the hospital, certain patients may receive intravenous drug therapy to dissolve blood clots (**thrombolytic therapy**). If started within six hours after the start of the heart attack, these drugs are successful in dissolving blood clots in about 80% of patients. If these drugs are given in a window 6–12 hours after the start of pain, the success rate drops to 50%. Thrombolytic therapy is not used if more than 12 hours has passed since chest pain started. Throughout treatment, the patient is monitored closely.

Additional treatment can include electric shock, additional drug therapy, **revascularization** procedures, percutaneous transluminal coronary angioplasty, and coronary artery bypass surgery. An electrical-shock device (defibrillator) may be used to restore a normal rhythm if the heart is fluttering and contracting uncontrollably (arrhythmia). Supplemental oxygen often is used to ease the heart's workload. If oxygen is used within hours of the heart attack, it may help limit damage to the heart. Additional drugs may be used to stabilize the patient and limit damage to the heart, including **aspirin**, anticoagulants, painkillers, tranquilizers, beta-blockers, ace-inhibitors, nitrates, rhythm-stabilizing drugs, and **diuretics**. Once patients have been stabilized, they are usually moved to the cardiac care unit (CCU) for special monitoring.

Drugs

To prevent additional heart attacks, aspirin and an anticoagulant drug often follow the thrombolytic drug. These help to prevent new blood clots from forming and existing blood clots from growing. **Anticoagulant drugs** help prevent the blood from clotting. The most common anticoagulants are heparin and warfarin. Heparin often is given intravenously while patients are in the hospital. Warfarin (Coumadin), taken orally, often is given later, and sometimes must be taken for life. Aspirin helps to prevent the dissolved blood clots from reforming.

To relieve pain, a nitroglycerine tablet taken under the tongue may be given. If the pain continues,

morphine sulfate may be prescribed. Tranquilizers such as diazepam (Valium) and alprazolam (Ativan) may be prescribed to lessen the **trauma** of a heart attack.

To slow the heart rate and give the heart a chance to heal, beta-blockers often are given intravenously right after the heart attack. These can also help prevent sometimes-fatal **ventricular fibrillation**. Beta-blockers include atenolol (Tenormin), metoprolol (Lopressor), nadolol, pindolol (Visken), propranolol (Inderal), and timolol (Blocadren).

Nitrates, a type of vasodilator, are given right after a heart attack to help improve the delivery of blood to the heart and ease **heart failure** symptoms. Nitrates include isosorbide mononitrate (Imdur), isosorbide dinitrate (Isordil, Sorbitrate), and nitroglycerin (Nitrostat).

When a heart attack causes an abnormal heartbeat, arrhythmia drugs may be given to restore and maintain the heart's normal rhythm. These include amiodarone (Cordarone), atropine, bretylium, disopyramide (Nor Pace), lidocaine (Xylocaine), procainamide (Procan), propafenone (Rythmol), propranolol (Inderal), quinidine, and sotalol (Betapace).

Angiotensin-converting enzyme (ACE) inhibitors reduce the resistance against which the heart beats and are used to manage and prevent heart failure. They are used to treat heart attack patients whose hearts do not pump well or who have symptoms of heart failure. Taken orally, they include Altace, Capoten, Lotensin, Monopril, Prinivil, Vasotec, and Zestril. Angiotensin receptor blockers, such as losartan (Cozaar), may be substituted.

Diuretics can help get rid of excess fluids that sometimes accumulate when the heart is not pumping effectively. They also help reduce **hypertension**. Usually taken orally, they cause the body to increase urine output. Common diuretics include: bumetanide (Bumex), chlorthalidone (Hygroton), chlorothiazide (Diuril), furosemide (Lasix), hydrochlorothiazide (HydroDIRUIL, Esidrix), spironolactone (Aldactone), and triamterene (Dyrenium).

Surgery

Percutaneous transluminal coronary angioplasty and coronary artery bypass surgery are invasive revascularization procedures that open blocked coronary arteries and improve blood flow. They usually are performed only on patients for whom clot-dissolving drugs do not work, who have poor **exercise stress** tests, poor left ventricular function, or ischemia (degraded flow to tissues). Generally, angioplasty is tried before coronary artery bypass surgery is attempted.

Percutaneous transluminal coronary angioplasty, usually called coronary angioplasty, is a procedure in which a catheter (a tiny plastic tube) tipped with a balloon is threaded from a blood vessel in the thigh or arm into the blocked artery. The balloon is inflated, which compresses the plaque to enlarge the blood vessel and open the blocked artery. The balloon is then deflated and the catheter is removed. Coronary angioplasty is performed in a hospital and generally requires a two-day stay. It is successful about 90% of the time. For one-third of patients, the artery narrows again within six months after the procedure. The procedure can be repeated. It is less invasive and less expensive than coronary artery bypass surgery. In many cases, stenting may be performed along with coronary angioplasty. A metal mesh stent may be inserted into the affected artery to keep it open.

In coronary artery bypass surgery, a detour is built around the coronary artery blockage using a healthy leg or chest wall artery or vein. The healthy vein then supplies oxygen-rich blood to the heart. Bypass surgery is major surgery done most often only when patients have blockages in two or three coronary arteries or severely narrowed left main coronary arteries, or who have not responded to other treatments. It is performed in a hospital under general **anesthesia** using a heart-lung machine to support the patient while the heart is stopped and a healthy vein is attached to the coronary artery. About 70% of patients who have bypass surgery experience full relief from angina; about 20% experience partial relief. Long term, symptoms recur in only about 3–4% of patients per year. Five years after bypass surgery, survival expectancy is 90%, at 10 years it is about 80%, at 15 years it is about 55%, and at 20 years it is about 40%.

There are several other surgical procedures for unblocking coronary arteries. These include **atherectomy**, for which the surgeon grinds out and removes strips of plaque from the blocked artery and laser angioplasty, where a catheter with a laser tip is inserted to burn or break down the plaque. After the artery is opened, a tiny metal tube called a stent may be implanted permanently to help the artery remain open.

Alternatives

Alternative therapies aim at preventing the progression of **heart disease** that leads to a heart attack. Changes in lifestyle can also prevent second heart attacks.

WWW.BOOKBAZ.IR

Herbal medicine offers a variety of remedies that may have a beneficial effect on coronary artery disease. Oats (Avena sativa), garlic (Allium sativum), and guggul (Commiphora mukul), may help reduce cholesterol; linden (Tilia europaea) and hawthorn (Crataegus spp.) are sometimes recommended to control high blood pressure, a risk factor for heart disease. Tea (Camellia sinensis), especially green tea, is high in **antioxidants**, which studies have shown may have a preventive effect against atherosclerosis.

Nutritional therapies have been shown to prevent coronary artery disease and stop, or even reverse, the progression of atherosclerosis. A low-fat, high-fiber diet is often recommended. It is essential to reduce the amount of meat and animal products consumed, as they are high in saturated fats. Whole grains, fresh fruits and vegetables, legumes, and nuts are recommended. Vitamin and mineral supplements that reduce, reverse, or protect against coronary artery disease include chromium; **calcium** and magnesium; B complex **vitamins**; the antioxidant vitamins B and E; L-carnitine; and zinc.

Yoga and other bodywork, massage, relaxation therapies, **aromatherapy**, and **music therapy** may also help by reducing stress and promoting physical and mental well-being. By evoking the body's relaxation response through **meditation** and deep breathing, blood pressure, metabolic rate, and heart rate can all be reduced.

Rehabilitation

Successful recovery from a heart attack requires a substantial amount of **rehabilitation**. Most patients follow a three-stage rehabilitation program. Phase 1 begins in the hospital with low-level exercise to prevent complications from prolonged bed rest. Phase 2 begins after hospital discharge and usually takes place in an outpatient rehabilitation setting. The goals of phase 2 are to increase physical endurance and to promote return to normal daily activities. Phase 3 continues in an outpatient setting. It begins from three to six months after the heart attack and may last up to one year. In phase 3, the level of exercise is gradually increased, ideally to the point where swimming, light jogging, or bicycling is possible. The effectiveness of rehabilitation, however, may be limited by other medical conditions.

Prognosis

Early recognition of a heart attack substantially improves survival. More than half of all people who have heart attacks die before they reach the hospital. Another 10% of patients die in the hospital. Of people who leave the hospital after a heart attack, 27% of men and 44% of women die within one year. Within six years, 23% of men and 31% of women have another heart attack, 13% of men and 6% of women experience sudden death, and about 20% have heart failure. People who survive a heart attack have a chance of sudden death that is 4–6 times greater than others and a chance of illness and death that is 2–9 times greater.

Possible complications from damage caused by having a heart attack include:

- Arrhythmias: abnormal heart rhythms of the heart muscle can occur due to abnormal electrical activity produced from a heart attack. These can be serious and sometimes fatal.
- Heart failure: the damage caused to the heart muscle can be so great that the remaining healthy muscle cannot perform an adequate job of pumping blood out of the heart.
- Heart rupture: the damaged portion of the heart can become so weakened that it ruptures, creating a hole in that degraded area.
- Valve problems: heart valves damaged during the heart attack can cause serious problems because they leak blood into areas normally not filled with blood from the source of the blood.

People who have a heart attack can lead full, active lives as long as they have a lifestyle that promotes a healthy heart and a positive mental attitude. Counseling and **cardiac rehabilitation** programs may greatly help with the physical and mental concerns one has after having a heart attack. Seeking out others that have experienced similar heart problems may also help.

Prevention

Many heart attacks can be prevented through a healthy lifestyle that reduces risk factors for developing coronary artery disease. For patients who have already had a heart attack, a healthy lifestyle, participation in a cardiac rehabilitation program, and carefully following doctor's orders may prevent another heart attack. A heart-healthy lifestyle includes eating a heart-healthy diet, regular exercise, maintaining a healthy weight, no **smoking**, moderate drinking, no illegal drugs, controlling high blood pressure, and managing stress.

Moderate drinking, for instance, is considered to be one drink a day at the maximum for women, and two drinks for men. One drink is equivalent to 12 oz.

KEY TERMS

Angina—Chest pain caused by diseased blood vessels restricting the flow of blood to the heart. Angina often is the first symptom of coronary artery disease.

Atherosclerosis—A process in which the walls of the coronary arteries thicken due to the accumulation of plaque in the blood vessels. Atherosclerosis is the cause of coronary artery disease.

Coronary arteries—The arteries that provide blood to the heart. The coronary arteries surround the heart like a crown, coming out of the aorta, arching down over the top of the heart and dividing into two branches. These arteries are the site where coronary artery disease occurs.

Myocardial infarction—The technical term for heart attack. Myocardial means heart muscle and infarction means death of tissue from lack of oxygen.

Plaque—A deposit of fatty and other substances that accumulate in the lining of the artery wall.

(355 mL) of beer, 4 oz. (118 mL) of wine, or 1.5 oz. (44 mL) of an 80-proof hard liquor.

A heart-healthy diet includes a variety of foods that are low in fat (especially saturated fat), low in cholesterol, and high in fiber; plenty of fruits and vegetables; and limited **sodium** (salt). Saturated fat raises cholesterol. Polyunsaturated and monounsaturated fats are relatively better for the heart. Fat should comprise no more than 30% of total daily calories. The American Heart Association has information on heart-healthy living on its website and publishes several heart-healthy cookbooks.

Cholesterol comes from eating foods such as meat, eggs, and other animal products. It also is produced in the liver. Soluble dietary fiber can help lower cholesterol. Cholesterol intake should be limited to about 300 mg per day. Many lipid-lowering drugs can reduce LDL-cholesterol by an average of 25% to 30% when combined with a low-fat, low-cholesterol diet. Fruits and vegetables are rich in fiber, vitamins, and **minerals**. They are also low in calories and nearly fat free. Vitamin C and beta-carotene, found in many fruits and vegetables, also are beneficial. Excess sodium increases the risk of high blood pressure. Many processed foods contain large amounts of sodium, which should be limited to a daily intake of 2,400 mg—about the amount in a teaspoon of salt. In the United States, cholesterol, fats, fiber, sodium, and calories are listed on nutritional labels of all processed foods.

Regular aerobic exercise can lower blood pressure, help control weight, increase HDL ("good") cholesterol, and reduce stress. Moderate intensity aerobic exercise lasting about 30 minutes four or more times per week is recommended for maximum heart health. Three 10-minute exercise periods also are beneficial. Aerobic exercise—activities such as walking, jogging, and cycling—uses the large muscle groups and forces the body to use oxygen more efficiently. It also can include everyday activities, such as active gardening, climbing stairs, or brisk housework. Any regular exercise, no matter how mild, is better than not exercising.

Maintaining a desirable body weight is important in preventing heart attacks. In 2013, over one-third of all adult Americans were obese (excessively overweight); specifically, the U.S. Centers for Disease Control and Prevention found that 35.7% of U.S. adults were obese. People who are 20% or more over their ideal body weight have an increased risk of developing coronary artery disease. Losing weight can help reduce total and LDL cholesterol, reduce **triglycerides**, and boost relative levels of HDL cholesterol. It also may reduce blood pressure.

Smoking tobacco products such as cigarettes has many adverse effects on the heart. It increases the heart rate, constricts major arteries, and can create irregular heartbeats. It also raises blood pressure, contributes to the development of plaque, increases the formation of blood clots, and causes blood platelets to cluster and impede blood flow. Quitting can repair heart damage caused by smoking; even heavy smokers can return to heart health, and the health of their lungs improves, too. Several studies have shown that ex-smokers face the same risk of heart disease as non-smokers within 5–10 years of quitting.

Drinking alcohol should always be done in moderation. Modest consumption of alcohol may protect against coronary artery disease; however, even small amounts of alcohol may have other negative effects depending on the individual's health status and medications being taken. The American Heart Association defines moderate consumption as roughly two cocktails, one 8-oz. (226-mL) glass of wine, or two 12-oz. (355-mL) glasses of beer for men; and one-half that amount for women. Excessive alcohol use is always

WWW.BOOKBAZ.IR

bad for the heart, and illegal drugs, such as methamphetamines and cocaine, can seriously harm the heart and cause a fatal heart attack.

High blood pressure, one of the most common and serious risk factors for coronary artery disease, can be controlled through lifestyle changes and medication. People with moderate hypertension may be able to lower it through dietary changes, such as reducing sodium intake combined with exercising regularly, managing stress, quitting smoking, and drinking alcohol in moderation. If these changes do not work, or if hypertension is severe, drugs that lower blood pressure may be prescribed.

Stress management means controlling mental and physical reactions to life's irritations and challenges. Techniques for controlling stress include taking life more slowly, spending time with family and friends, thinking positively, getting enough sleep, exercising, and practicing relaxation techniques.

Daily aspirin therapy has been proven to help reduce blood clots associated with atherosclerosis. It also can lower the risk of strokes.

Heart block

Definition

Heart block is a problem that sometimes occurs with the electrical system of the heart, which controls the rate (number of beats per minute) and rhythm (regular or irregular pattern of pulses) of heartbeats. It refers to a delay or disruption in the normal series of electrical impulses that cause the heart to beat. With heart block, the heart's rhythm is slower than normal, what is called bradycardia. As a type of arrhythmia (an irregularity of the rhythm of the heart), heart block is further classified as first-, second-, or third-degree block.

Description

The muscles of the heart contract in a rhythmic order for each heartbeat because electrical impulses travel along a specific route called the conduction

system. This system controls the electrical signal as it moves from the upper chambers of the heart to the lower ones. Specifically, the sinoatrial (SA) node, located at the top of the right atrium, controls the pace of the heart. The electrical signal travels through the atria (the right and left atrium) and into the atrioventricular (AV) node, which is the main junction of the conduction system. After passing through the AV node, the electrical signal goes through the bundle of His, a bundle of heart muscle cells that are produced to transmit electrical impulses from the AV node to the point of the apex of the fascicular branches. From there, a signal sends the electricity into the Purkinje fibers and then onto the right and left ventricles.

As the electrical signal travels into the ventricles, it causes the heart to contract and, thus, to pump blood. However, just as on a highway, there are occasionally some delays getting the impulse from the top of the heart to the bottom of it. These delays or interruptions are classified according to their severity.

In first-degree heart block—the least severe form of heart block—the electrical signal is slowed a little as it travels along the defective part of the conduction system. The signal arrives, but it arrives late as it travels from the atrium to the ventricle. Thus, all of the signals arrive at their destination as they should, only the signals are delayed (slowed) in the process.

In second-degree heart block, not every impulse reaches its destination. The block may affect every other beat, every second or third beat, or be rare. If the blockage is frequent, it results in an overall slowing of the heart called bradycardia. Second-degree heart block is further divided into two subtypes: Mobilz type I (also called Type I) and Mobilz type II (Type II). With second-degree Type I, also known as Wenchebach's block, electrical signals are delayed progressively until a skipped heartbeat occurs. In second-degree Type II, the more serious of the two subtypes, the pattern of electrical signals is less regular than with Type I. Although more serious, it occurs less commonly than Type I. People with no heart block while they are awake, sometimes have Type I while they sleep. Those with Type II usually need a pacemaker, whereas those with Type I normally do not need one. Further, people with second-degree Type II often progress to third-degree heart block.

Third-degree block, also called complete heart block or complete atrioventricular (AV) block, is the most serious of the three types of heart block. When no signals can travel from the atria, through the AV node, and into the ventricles, the heart uses its backup impulse generator in the lower portion of the heart (within the ventricles themselves). These impulses (called junctional or ventricular escape beats) usually prevent the heart from stopping entirely; however, they are too slow to be called an effective pump. As a result, third-degree block can result in lightheadedness and **fatigue** and eventually in sudden cardiac arrest and even death. Emergency treatment is essential to prevent third-degree block from seriously harming the patient. In many cases, a temporary pacemaker may be used until a permanent one can be inserted into the body.

Risk factors

First-degree heart block occurs more frequently in conditioned athletes, teenagers, young adults, and people with a highly active vagus nerve (the tenth cranial nerve; also called the pneumogastric nerve) than it does in other groups of people. Further, an increased risk of heart block is likely to occur with the following conditions or scenarios:

- aging
- heart attacks
- heart disease such as coronary artery disease, rheumatic heart disease, and sarcoidosis
- heart failure
- heart valve abnormalities
- heart valve surgery
- Lyme disease
- use of some medications or contact with toxic substances

Demographics

Congenital heart block can happen to any baby regardless of the age, ethnic background, or medical condition of the mother. However, babies born to women with autoimmune diseases are at greater risk of getting congenital heart block than are other babies. Parents with a congenital heart defect are more likely to pass on this problem to their children than are parents without these conditions. **Congenital heart disease**, which is a grouping of medical disorders that includes heart block, affects about one in 100 children. About half a million American adults have congenital **heart disease**. Further, about 17 million people die of cardiovascular disease each year around the world, according to the World Health Organization. Heart block is included within cardiovascular disease.

Acquired heart block can happen in people of any age, ethnic origin, gender, or other characteristics. It is more common in older people because many of the

WWW.BOOKBAZ.IR

risk factors for heart disease are more commonly found in elderly people.

Causes and symptoms

Heart block can be present before or just after a baby is born, what is called congenital heart block. Various diseases can occur during **pregnancy** that cause heart block. One such group is autoimmune diseases, which a mother can pass on to her baby through her placenta. Autoimmune diseases, such as lupus, cause antibodies to be produced by the body, which are then used to damage tissues and cells of the body.

Some congenital heart defects, present when the body is born, can adversely affect the structure of the heart and can also cause heart block.

Heart block can also be found much later in life, in what is termed acquired heart block. For instance, it can happen when damage to the heart occurs from diseases, medicines, and surgeries. A **heart attack** is one such example of acquired heart block and the one that is most common in humans. Coronary heart disease, **myocarditis** (inflammation of the heart muscle), and **heart failure** are three other causes of acquired heart block. The most common cause of heart block is the scarring of the heart's electrical system, which is caused by **aging**. Certain medicines can also increase one's risk for heart block. Such medicines include **beta blockers**, **calcium channel blockers**, and digitalis. Of the two subtypes of heart block, acquired heart block occurs more commonly than congenital heart block.

First-degree heart block is fairly common. It is seen in teenagers, young adults, and well-trained athletes. The condition may be caused by **rheumatic fever**, some types of heart disease, and by various drugs. First-degree heart block produces few or no symptoms.

Second-degree heart block can produce the skipping of one or more heartbeats. A person may also feel dizzy or faint at times. Some cases of second-degree heart block may benefit from an artificial pacemaker. Second-degree block occasionally progresses to third-degree block.

Third-degree heart block is a serious condition that affects the heart's ability to pump blood effectively. Symptoms include **fainting**, **dizziness**, fatigue and tiredness, **shortness of breath**, chest **pain**, and sudden heart failure. If the ventricles beat more than 40 times per minute, symptoms are not as severe but include tiredness, low blood pressure on standing, and shortness of breath.

Young children who have received a forceful blunt chest injury can experience first- or second-degree heart block.

Diagnosis

Diagnosis of first- and second-degree heart block is made by observing it on an electrocardiograph (ECG). The ECG is performed to analyze the electrical activity within the heart. It will show how fast or slow the heart is beating and whether its rhythm is steady or irregular. The strength and timing of the heart's electrical signals will also be shown by an ECG. One type of ECG is a Holter monitor, which constantly records electrical signals from the heart for an extended period, usually from 24 to 48 hours. An event monitor is an abbreviated version of the Holter monitor. It only records data at specific times within a certain period. Along with an ECG, an electrophysiology study may be performed. This involves passing a thin, flexible wire through a vein in the upper thigh or arm and into the heart. A sensor at the end of the wire records the electrical signals flowing through the heart. This data is used by medical professionals to provide the best treatment for each patient with heart block.

First-degree heart block may not cause any serious symptoms, whereas second-degree block may make one dizzy or faint because the heart is skipping one or more beats. Because third-degree heart block limits the ability of the heart to pump blood, it results in noticeable symptoms such as fainting, fatigue, dizziness, and sudden heart failure, which require immediate medical care. A **physical examination**, a complete evaluation of one's family and medical history, and ECG confirm the presence of heart block. Cardiologists, pediatric cardiologists, and electrophysiologists (those doctors who specialize in the electrical system of the heart) may help to complete the diagnosis.

Treatment

Treatment for heart block depends on the type of heart block being treated. For first-degree heart block, treatment may not be needed. Some second- and almost all third-degree heart blocks require an artificial pacemaker, which helps the heart to beat with a normal rate and rhythm. The pacemaker is placed under the skin of the chest or abdomen so that it can use its electrical pulses to control the heart in a normal fashion. In an emergency, a temporary pacemaker can be used until an implanted device is advisable. Most people with third-degree heart block need the pacemaker for the rest of their lives.

KEY TERMS

Arrhythmia—Any problem with the rate or rhythm of the heartbeat.

Atrioventricular node (AV node)—Highly specialized area of the heart muscle that transmits electrical impulses.

Bradycardia—A slow heart rate, usually under 60 beats per minute.

For pregnant women with one of a number of autoimmune diseases, the doctor is likely to prescribe medicine to reduce the risk of the fetus of developing heart block.

Prognosis

Most people with first-degree heart block and those with second-degree Type I heart block do not even know they have it. Some people with second-degree Type II and third-degree heart block have their heart restored to its normal, dependable rhythm and live full and comfortable lives. If a pacemaker does not properly control the rhythm of their hearts, those with third-degree heart block may find that the heart is limited with respect to its ability to pump blood. However, in most cases, a pacemaker restores function to the heart. All types of heart block increase the risk for other **arrhythmias**.

If problems with acquired and congenital heart block are solved, patients can lead a normal and healthy life. Those that must wear a pacemaker can live relatively normal lives by taking a few precautions. First, they must avoid prolonged contact with electrical devices, especially those that produce a strong magnetic field. Such devices can interfere with the pacemaker, sometimes keeping it from performing its important function. Also, they must make sure that attending physicians and their staff know about the pacemaker. In addition, they need to make sure the security screening personnel at the airport know about the pacemaker before going through their screening devices.

Prevention

To help lower one's chances of getting heart block, the New York University's Langone Medical Center suggests that the following be done:

- Obtain treatment for any condition that may cause heart problems or heart disease. This will help prevent heart block.
- If possible, avoid medications that can cause heart block, such as beta blockers, calcium channel blockers, and digitalis.
- Maintain a healthy weight and lifestyle. Get regular exercise, eat a heart-healthy diet, and minimize stress.
- Avoid excessive consumption of alcohol and caffeine.
- Stop smoking.

REVISED BY WILLIAM A. ATKINS, B.B., B.S., M.B.A.

Heart catheterization *see* **Cardiac catheterization**

Heart disease

Definition

Heart disease, sometimes also called coronary heart disease and cardiovascular disease, is a group of conditions affecting the structure and functions of the heart. The four primary conditions that comprise heart disease are **coronary artery disease**, **heart attack**, **congenital heart disease**, and rheumatic heart disease. Other diseases include **angina** (chest **pain**), aorta disease and **Marfan syndrome**, arrhythmia (irregular heartbeat), congenital heart disease, heart muscle disease (**cardiomyopathy**), heart valve disease, pericardial disease, and **vascular disease** (blood vessel disease). In the United States, heart disease is the leading cause of death for both men and women.

Description

The heart is a muscle that gets energy from blood carrying oxygen and nutrients. Having a constant supply of blood keeps the heart working properly. Most people think of heart disease as one condition. However, heart disease is a group of conditions affecting the structure and functions of the heart and has many causes. Coronary artery disease (CAD) is the most common of these conditions and occurs when blood vessels in the heart become blocked or narrowed. This blockage limits the flow of blood through the coronary arteries, the major arteries supplying oxygen-rich blood to the heart. The coronary arteries expand when the heart is working harder and needs more oxygen. If the arteries are unable to expand, the heart is deprived of oxygen (myocardial ischemia). When the blockage is limited, chest pain or pressure called angina may occur. When the blockage cuts off the blood flow, the result is heart attack (myocardial infarction or heart muscle death).

A normal heart is a strong muscular pump. It weighs between 7 and 15 oz. (200 and 425 g) and is a little larger than the size of an adult fist. During an average lifetime, the human heart will beat more than 2.5 billion times. The average heart beats about 100,000 times each day and pumps about 1,900 gal. (7,200 L) of blood. The heart sits between the lungs in the middle of the chest, behind and slightly to the left of the breastbone. A double-layered membrane called the pericardium surrounds the heart like a sac. Blood loaded with oxygen comes from the lungs and enters the heart. To function, the heart needs a continuous supply of oxygen and nutrients, which it receives from the blood that is pumped through the coronary arteries. The heart and circulatory system make up the cardiovascular system. The heart pumps blood to the organs, tissues, and cells of the body, delivering oxygen and nutrients to every cell and removing carbon dioxide and waste products made by those cells. Oxygen-rich blood is carried from the heart to the rest of the body through a complex network of arteries, arterioles, and capillaries. Oxygen-poor blood is carried back to the heart through veins.

Prevalence of heart disease in the United States[1]

	African American		Caucasian	
	Females	Males	Females	Males
Coronary heart disease	7.1%	6.8%	4.6%	8.2%
Heart attack	2.3%	3.9%	1.5%	4.4%
Angina pectoris	5.4%	2.4%	2.3%	3.3%
Total cardiovascular disease	**48.9%**	**44.9%**	**32.4%**	**36.6%**

(Table by PreMediaGlobal. © Cengage Learning®.)

Coronary artery disease

Healthy coronary arteries are open, elastic, smooth, and slick. The artery walls are flexible and expand to let more blood through when the heart needs to work harder. The disease process is thought to begin with an injury to the linings and walls of the arteries. This injury makes them susceptible to atherosclerosis and production of **blood clots** (thrombosis).

Coronary artery disease (CAD) is a condition in which plaque builds up inside the coronary arteries. These arteries supply the heart muscle with oxygen-rich blood. Plaque is made of fat, **cholesterol**, **calcium**, and other substances found in the blood. When plaque builds up in the arteries, the condition is called atherosclerosis, commonly called hardening of the arteries. Plaque narrows the arteries and reduces blood flow to the heart. It also makes it more likely that blood clots will form in arteries. Blood clots can partially or completely block blood flow. When coronary arteries are narrowed or blocked, oxygen-rich blood cannot reach the heart. This can cause angina or a heart attack. Angina is chest pain or discomfort that occurs when not enough oxygen-rich blood is flowing to an area of the heart. Angina may feel like pressure or squeezing in the chest. The pain also may occur in the shoulders, arms, neck, jaw, or back. A heart attack occurs when blood flow to an area of the heart is completely blocked. This prevents oxygen-rich blood from reaching that area of heart and causes it to die. Without quick treatment, a heart attack can lead to serious problems and even death. Over time, CAD can weaken the heart and lead to **heart failure** and **arrhythmias**. Heart failure is a condition in which the heart cannot pump enough blood throughout the body. Arrhythmias are irregularities with the speed or rhythm of the heartbeat.

Heart attack (myocardial infarction)

A heart attack (myocardial infarction) occurs when the blood supply to the heart is slowed or stopped because of a blockage. Atherosclerosis, the narrowing of coronary arteries due to plaque buildup, causes more than 90% of heart attacks. A heart attack may also occur when a coronary artery temporarily contracts or goes into a severe spasm, effectively shutting off the flow of blood to the heart. The length of time the blood supply is cut off determines the amount of damage to the heart.

Congenital heart disease

Congenital means existing at birth. A congenital heart defect happens when the heart or the blood vessels near the heart do not develop normally before birth. Congenital heart defects are present in about 1% of live births and are the most frequent congenital malformations in newborns. In most cases, researchers do not know why they happen. Some causes are viral infections, certain conditions such as **Down syndrome**, and drug abuse by the mother during **pregnancy**, especially of alcohol, cocaine, and methamphetamines.

Rheumatic heart disease

Rheumatic heart disease describes a group of acute (short-term) and chronic (long-term) heart disorders that can occur as a result of **rheumatic fever**. One common result of rheumatic **fever** is heart valve damage. Due to the control of rheumatic fever in the United States and most developed countries, it is relatively rare in these regions but is still a significant heart disease in parts of Africa, Asia, and South America. Rheumatic fever is an inflammatory disease that may affect many connective tissues of the body, especially those of the heart, joints, brain, or skin. It

WWW.BOOKBAZ.IR

usually starts as a **strep throat** (streptococcal) infection. Anyone can get acute rheumatic fever, but it usually occurs in children between the ages of five and 15 years. About 60% of people with rheumatic fever develop some degree of subsequent heart disease.

Demographics

The Heart Foundation states that "Every 33 seconds someone in the United States dies from cardiovascular disease, which is roughly the equivalent of a September 11th-like tragedy repeating itself every 24 hours, 365 days a year." As of 2011, the U.S. Centers for Disease Control and Prevention (CDC) stated that 26.5 million noninstitutionalized adults (or 11.5%) have been diagnosed with heart disease in the United States. Heart disease is the leading cause of death in the United States, and it is a major cause of disability. As of 2013, the CDC stated that about 600,000 people die of heart disease in the United States each year, about 25% of all U.S. deaths.

The CDC also reported that coronary heart disease is the principal type of heart disease, responsible for about 385,000 people dying annually. In addition, about 715,000 Americans have a heart attack each year, with about 525,000 people having it for the first time and the other 190,000 people having had one or more previous heart attacks. The CDC stated that coronary heart disease by itself costs the United States about $108.9 billion each year, which includes the costs of healthcare services, medications, and lost productivity at work.

Men are slightly more likely to develop heart disease than women. An increasing number of women are experiencing heart disease, but they continue to be under-diagnosed. For both genders, the risk of heart disease increases with age. In the United States, the percentages of deaths caused by heart disease by ethnicity are: American Indians or Alaska Natives, 18.0%; Hispanics, 20.8%; Asians or Pacific Islanders, 23.2%; African Americans, 24.5%; and whites, 25.1%. Overall, heart disease is the cause of 25.0% of all deaths in the United States each year.

Internationally, the World Health Organization (WHO) stated that cardiovascular disease (CVD) kills about 17.3 million people each year, mostly from heart attacks and strokes. Of that number, 4.7 million died in the Western Pacific, 4.6 million in Europe, 3.6 million in South-East Asia; 1.9 million in the Americas, 1.3 million in Africa, and 1.2 million in the East Mediterranean. By 2020, heart disease and **stroke** were predicted to become the leading cause of both death and disability worldwide, with the number of fatalities projected to increase to over 20 million a year and by 2030 to over 24 million a year. The WHO stated that heart disease is a "global epidemic".

Causes and symptoms

The causes and symptoms of heart disease vary depending on the specific type, such as coronary artery disease, heart attack, congenital heart disease, and rheumatic heart disease.

Coronary artery disease

Over many years, plaque builds up on artery walls. Plaque is a sticky, yellow substance made of fatty substances such as cholesterol, as well as calcium and waste products from cells. It narrows and clogs the arteries, slowing the flow of blood. The process is called atherosclerosis, a slow, progressive condition that may begin as early as childhood and occur anywhere in the body but usually affects large and medium-sized arteries. Atherosclerotic plaques often form blood clots that can also block the coronary arteries (coronary thrombosis). Sometimes plaque in an artery can rupture. The body's repair system in turn creates a blood clot to heal the wound. The clot, however, can block the artery, leading to a heart attack or stroke.

Congenital defects and **muscle spasms** of arteries or heart muscles also block blood flow. Some research indicates that infection from organisms such as chlamydia bacteria may be responsible for some cases of heart disease.

Early warning signs may include **fatigue**, pain, and **dizziness**, as well as the symptoms associated with angina such as a squeezing, suffocating, or burning feeling in the chest that tends to start in the center of the chest but may move to the arm, neck, back, throat, or jaw. Women are more likely to experience atypical symptoms, such as vague chest discomfort.

Heart attack (myocardial infarction)

A heart attack occurs when the blood supply to the heart is partially or completely blocked. Symptoms include pain in the chest, neck, jaw, shoulder, arms or back, sudden discomfort or pain (especially in the chest) that does not go away, difficulty breathing, nausea, sweating, and **anxiety**.

Congenital heart disease

Congenital heart disease is caused by a defect in the heart at birth. The most common symptoms of congenital heart defects are a heart murmur; a bluish

tint to the skin, lips, or fingernails; fast breathing; **shortness of breath**; and fatigue, especially during **exercise** or physical activity.

Rheumatic heart disease

It may take several years after an episode of rheumatic fever for valve damage to develop or symptoms to appear. **Antibiotics** can prevent streptococcal infection from developing into rheumatic fever. Any child with a persistent **sore throat** should have a **throat culture** taken to check for strep infection. Penicillin or another antibiotic usually prevents strep throat from developing into rheumatic fever. Symptoms of heart valve problems, which are often the result of rheumatic heart disease, can include chest pain, excessive fatigue, heart **palpitations** (when the heart flutters or misses beats), a thumping sensation in the chest, shortness of breath, and swollen ankles, wrists, or stomach.

Major risk factors

A number of major contributing risk factors increase the chance of developing heart disease. Some of these can be changed by lifestyle changes and some cannot. The greater the number of risk factors, the greater the chance of developing heart disease. Major risk factors significantly increase the chance of developing heart disease. These include:

- Heredity. People whose parents have heart disease are more likely to develop it. African Americans are also at increased risk because they experience a high rate of severe hypertension.
- Gender. Men are more likely to have heart attacks than women and have them at a younger age. Above the age of 60 years, however, women have heart disease at a rate equal to that of men.
- Age. Men who are 45 years of age and older and women who are 55 years of age and older are more likely to have heart disease. Occasionally, heart disease may strike men or women in their 30s. People more than 65 years old are more likely to die from a heart attack. Older women are twice as likely as older men to die within a few weeks of a heart attack.
- Smoking. Smoking tobacco products increases both the chance of developing heart disease and the chance of dying from it. Smokers are more than twice as likely as nonsmokers to have a heart attack and are two to four times more likely to die from it.
- High cholesterol levels. Dietary sources of cholesterol are meat, dairy food, eggs, and other animal-fat products. The body also produces cholesterol. Age, body fat, diet, exercise, heredity, and gender affect one's level of blood cholesterol. For typical, healthy patients, the American Heart Association (AHA) recommends total blood cholesterol below 200 milligrams per deciliter (mg/dL), which places individuals at a comparatively low risk for coronary heart disease. For these individuals, a total cholesterol level of from 200–239 mg/dL is considered borderline high-risk, and a level of 240 mg/dL or above is considered high risk and doubles the risk for coronary heart disease. Persons with such risk factors as elevated low-density lipoprotein (LDL cholesterol, or "bad" cholesterol) levels, low high-density lipoprotein (HDL or "good" cholesterol) levels, or high triglyceride levels should consult with their doctor about what their target cholesterol level should be.
- High blood pressure. High blood pressure makes the heart work harder and weakens it over time. It increases the risk of heart attack, stroke, kidney failure, and congestive heart failure. A blood pressure of 140 over 90 millimeters of mercury (mmHg) or above is considered high. The risk of heart attack or stroke is raised several times for people with high blood pressure combined with obesity, smoking, high cholesterol levels, or diabetes. Nearly one-third of American adults have high blood pressure.
- Lack of physical activity. Lack of exercise increases the risk of heart disease. Even modest physical activity, such as walking, is beneficial if done regularly.
- Diabetes mellitus. The risk of developing heart disease is seriously increased for diabetics. About two-thirds of people who have type I or type II diabetes die as the result of a heart attack or stroke.

Contributing risk factors

Numerous contributing risk factors have been linked to heart disease. These include:

- Obesity. Excess weight increases the strain on the heart and increases the risk of developing heart disease even if no other risk factors are present. Obesity increases blood pressure and blood cholesterol and can lead to diabetes.
- Hormone replacement therapy (HRT). Although physicians once believed that HRT could help prevent heart disease in women, the Women's Health Initiative (WHI) released information in 2002 and 2003 showing that use of combined hormones (estrogen and progestin) is harmful in women who already have coronary artery disease. As of 2013, it continued to be debated whether HRT, and estrogen in particular, provides some protection against heart disease when a woman takes it soon after going through menopause. For instance, the American

WWW.BOOKBAZ.IR

College of Obstetricians and Gynecologists stated in June 2013: "Menopausal hormone therapy should not be used for the primary or secondary prevention of coronary heart disease at the present time. Evidence is insufficient to conclude that long-term estrogen therapy or hormone therapy use improves cardiovascular outcomes." The organization added: "Nevertheless, recent evidence suggests that women in early menopause who are in good cardiovascular health are at low risk of adverse cardiovascular outcomes and should be considered candidates for the use of estrogen therapy or conjugated equine estrogen plus a progestin for relief of menopausal symptoms. There is some evidence that lends support to the 'timing hypothesis,' which posits that cardiovascular benefit may be derived when estrogen therapy or hormone therapy is used close to the onset of menopause, but the relationship of duration of therapy to cardiovascular outcomes awaits further study."

- Stress and anger. Some scientists contend that poorly managed stress and anger can contribute to the development of heart disease and increase the blood's tendency to form clots (thrombosis). Stress increases the heart rate and blood pressure and can injure the lining of the arteries.
- Chest pain (angina). Angina is the main symptom of coronary heart disease, but this pain is not always present. Other symptoms include shortness of breath, chest heaviness, tightness, pain, a burning sensation, squeezing, or pressure either behind the breastbone or in the left arm, neck, or jaws. According to the American Heart Association, 64% of women and 50% of men who died suddenly of heart disease had no previous symptoms of the disease.

Diagnosis

Diagnosis begins with a doctor's review of the medical history, discussion of symptoms, listening to the heart, and performing basic screening tests. These tests measure blood lipid levels, blood pressure, fasting blood-glucose levels, weight, and other indicators. Other diagnostic tests include coronary **angiography**, **echocardiography**, resting and exercise electrocardiograms, and radionuclide scans. The treadmill exercise (**stress**) test is an appropriate screening test for those with high-risk factors even though they feel well.

Angiogram

Coronary angiography is considered the most accurate method for making a diagnosis of heart disease, but it is also the most invasive. This test involves taking x-ray pictures of the coronary arteries and the vessels that supply blood to the heart. During coronary angiography the patient is awake but sedated. The cardiologist inserts a catheter into a blood vessel and guides it into the heart. A contrast dye (a radiopaque substance that is visible on an x-ray scan) is injected into the catheter and x rays are taken. This dye makes the blood vessels visible when an x ray is taken of them. Angiography allows doctors to clearly see how blood flows into the heart, which helps them to pinpoint problems with the coronary arteries. Angiography may be recommended for patients with angina or those with suspected coronary artery disease. The test gives doctors valuable information on the condition of the coronary arteries, such as atherosclerosis, regurgitation (blood flowing backwards through the heart valves), or pooling of blood in a chamber because of a valve malfunction. Coronary angiography is performed in a **cardiac catheterization** laboratory in either an outpatient or an inpatient surgery unit.

Radionuclide angiography enables physicians to see the blood flow of the coronary arteries. Nuclear scans are performed by injecting a small amount of radiopharmaceutical, such as thallium, into the bloodstream. As the patient lies on a table, a camera that uses gamma rays to produce an image of the radioactive material passes over the patient and records pictures of the heart. Radionuclide angiography is usually performed in a hospital's nuclear medicine department. The radiation exposure is about the same as that in a chest x ray.

Echocardiogram

An echocardiogram uses sound waves (**ultrasound**) to create a picture of the heart. The recorded waves show the shape, texture, and movement of the heart valves, as well as the size of the heart chambers and how well they are working. A technician applies gel to a hand-held transducer and then presses it against the patient's chest. The heart's sound waves are converted into an image that can be displayed on a monitor. An echocardiogram may be done to determine whether a stroke was caused by a heart condition and can also help determine if there is a risk of blood clots forming in the heart. It may also be recommended if the patient is experiencing abnormal heart sounds, shortness of breath, palpitations, angina, or has a history of stroke. It is very useful in diagnosing heart valve problems. It does not reveal the coronary arteries themselves but can detect abnormalities in the heart wall caused by heart disease. Typically performed in a doctor's office or outpatient facility, the test takes 30 to 60 minutes.

Electrocardiogram

An electrocardiogram (ECG or EKG) is a test that checks how the heart is functioning by measuring the electrical activity of the heart. Electrodes are placed on the patient's chest, arms, and legs. They send impulses of the heart's activity through an oscilloscope (a monitor) to a recorder that traces them on paper. With each heartbeat, an electrical impulse (wave) travels through the heart. This wave causes the muscle to squeeze and pump blood from the heart. By measuring how long the electrical wave takes to pass through the heart, a cardiologist can determine if the electrical activity is normal, fast, or irregular. The cardiologist may also be able to determine if the heart is enlarged or overworked. It may be recommended if the patient is experiencing arrhythmia, palpitations, dizziness, excessive fatigue, or angina. An ECG is used for the following reasons:

- Detect abnormal heart rhythms that may have caused blood clots to form
- Detect heart problems, including a recent or ongoing heart attack, abnormal heart rhythms (arrhythmias), coronary artery blockage, areas of damaged heart muscle (from a prior heart attack), enlargement of the heart, and inflammation of the sac surrounding the heart (pericarditis)
- Detect non-heart conditions such as electrolyte imbalances and lung diseases
- Monitor recovery from a heart attack, progression of heart disease, or the effectiveness of certain heart medications or a pacemaker
- Rule out hidden heart disease in patients about to undergo surgery

Exercise stress test

This test measures how the heart and blood vessels respond to exertion when the patient is exercising on a treadmill or a stationary bike. It can be performed in a physician's office or outpatient facility.

Treatment

Heart disease can be treated many ways. The choice of treatment depends on the patient and the severity of the disease. Treatments include lifestyle changes, drug therapy, and coronary artery bypass surgery. These, however, are not a cure. Heart disease is a chronic condition requiring lifelong care.

Medications

People with moderate heart disease may gain adequate control through lifestyle changes and drug therapy. Drugs such as nitrates, beta-blockers, and **calcium channel blockers** relieve chest pain and complications of heart disease, but they cannot clear blocked arteries. Nitrates improve blood flow to the heart, and beta-blockers reduce the amount of oxygen required by the heart during stress. Calcium channel blockers help keep the arteries open and reduce blood pressure. **Aspirin** helps prevent blood clots from forming on plaques, reducing the likelihood of a heart attack and stroke. Cholesterol-lowering medications are also indicated in many cases.

ANTIPLATELETS. Antiplatelets help prevent dangerous blood clots from forming. They may be used to reduce the risk of clot-induced heart attack or stroke, which is called preventive or prophylactic treatment. One of the most common antiplatelets is aspirin. Ticlopidine (Ticlid) may be prescribed to stroke survivors or those who are at high risk of stroke, particularly if they are not able to take aspirin. Clopidogrel (Plavix) is an antiplatelet drug that is effective in preventing strokes and heart attacks and is often prescribed for patients who receive a coronary stent. Dipyridmalole (Persantine) may also be given with other antiplatelet or anticoagulant medications. It can also be given by injection during tests on the heart.

ACE INHIBITORS. Angiotensin converting enzyme (ACE) inhibitors are usually given to people with high blood pressure, **congestive heart failure**, or people with a high likelihood of developing coronary artery disease. They may also be given to people after a heart attack to prevent further complications and to people living with congestive heart failure. They help control blood pressure to make it easier for the heart to pump. ACE inhibitors may also make people with CAD feel less tired and short of breath, reduce the time they spend in a hospital, and help them live longer lives. ACE inhibitors have been shown to reduce the risk of heart attack, stroke, and death in people with a history of coronary artery disease. Since ACE inhibitors are used to control and prevent conditions of the heart, they are usually prescribed for the long term.

BETA BLOCKERS. **Beta blockers** are used to treat high blood pressure, congestive heart failure, abnormal heart rhythms, and chest pain. They are sometimes used to prevent future heart attacks in someone who has had a heart attack and to treat **tremors** caused by an overactive thyroid, as well as anxiety or migraines. Beta blocker is short for beta-adrenergic blocking drugs. Beta blockers block the responses

WWW.BOOKBAZ.IR

from the beta nerve receptors. This slows the heart rate and lowers blood pressure to reduce the workload on the heart.

CALCIUM CHANNEL BLOCKERS. Calcium channel blockers, sometimes called calcium channel antagonists, are used to control high blood pressure, chest pain caused by coronary artery disease, and irregular heartbeats. Calcium channel blockers are often taken in combination with beta blockers or **diuretics** to help reduce blood pressure. Calcium channel blockers are **vasodilators**, which means they widen (dilate) blood vessels, letting blood flow through more easily. By relaxing blood vessels, the blood pressure drops, and the heart does not have to work as hard.

NITRATES. Nitrates are vasodilators and can be used to prevent chest pain, limit the number of angina attacks, relieve the pain of a current attack, or treat the symptoms of congestive heart failure. Nitroglycerin is a type of nitrate.

MEDICINES FOR HEART ATTACK (MYOCARDIAL INFARCTION). When someone is experiencing a heart attack or believes they are, they should seek immediate emergency help. In the United States, they should call or have someone else call 911 and request paramedics or emergency medical technicians (EMTs). Most fire departments in the United States and Canada have paramedics and/or EMTs. Doctors also recommend that at the first sign of a heart attack, the patient chew and swallow an adult (325 mg) aspirin, which can help improve blood flow to the heart. Only aspirin can improve blood flow; no other pain medications, such as **acetaminophen** (Tylenol) or ibuprofen (Advil), will work. Until medical help arrives, the patient should sit or lie down. If these individuals are on the drug nitroglycerine, they should take a normal dose. Following a heart attack, patients may be put on nitrates, ACE inhibitors, beta-blockers, and antiplatelets. Other drugs are thrombolytic drugs, used to dissolve blood clots that are blocking the coronary arteries, and anticoagulants, used to thin the blood and prevent clots from forming in the arteries. Surgical treatments include **angioplasty** and coronary bypass.

MEDICINES FOR CONGENITAL HEART DISEASE. The heart defects of congenital heart disease are treated with several medications, including ACE inhibitors, beta blockers, diuretics, and **digoxin**. Diuretics act on the kidneys to produce more urine and remove excess salt and water from the body. By decreasing water and salt, diuretics lower blood pressure and help reduce the workload on the heart. This may make it easier for the heart to pump, improve shortness of breath, reduce swelling and bloating, reduce the time spent in a hospital, and help patients to live longer lives. Digoxin helps the heart pump stronger and slows down the heart rate to improve its pumping action.

In many cases, the strain to the heart requires procedures that either fix holes between the chambers, replace valves, or repair or reconnect major blood vessels. In severe cases, heart **transplant surgery** may be needed. Several other surgical procedures can be used to repair and correct congenital heart defects They include the following:

- Cardiac catheterization is often used to repair simple holes in the heart. A catheter (thin tube) is inserted into a blood vessel in the groin or arm and guided to the heart so that a surgeon can insert a plug inside the hole to repair it.
- Angioplasty is used to repair defective cardiac valves that can be either too narrow or leaky. A tiny balloon is guided to the heart inside a catheter (a thin tube). When the balloon is inflated, it can stretch the opening of a narrowed heart valve and restore normal blood flow. It is removed once blood flow returns.

Medicines for rheumatic heart disease

If heart damage from rheumatic fever is identified in childhood or young adulthood, daily antibiotics may be required until the age of 25 or 30 years to help prevent recurrence of rheumatic fever and avoid the development of infective bacterial **endocarditis**, an infection of the heart valves or lining of the heart. Additional treatment will depend on the type of heart damage. Surgery may be required to repair or replace damaged heart valves. In rare cases, heart transplant surgery may be recommended.

Medical procedures

Several procedures are used to reduce the risk from heart disease. These include angioplasty with stent, coronary artery bypass surgery, and counter pulsation.

ANGIOPLASTY WITH STENT. Percutaneous coronary intervention (PCI), commonly called angioplasty with a stent, is a nonsurgical procedure that uses a catheter (a thin flexible tube) to insert a small structure called a stent (a small tubular structure made of stainless steel or plastic) to open up blood vessels in the heart that have been narrowed by plaque buildup. PCI improves blood flow, thus decreasing heart-related chest pain, making patients feel better and increasing their ability to be physically active. During the procedure, a catheter is inserted into the blood vessels either in the groin or in the arm. Using a special type of x-ray scan called fluoroscopy, the catheter is threaded

through the blood vessels into the heart where the coronary artery is narrowed. When the tip is in place, a balloon tip covered with a stent is inflated. The balloon tip compresses the plaque and expands the stent. Once the plaque is compressed and the stent is in place, the balloon is deflated and withdrawn. The stent stays in the artery, holding it open. The doctor may use a coated stent or a bare metal stent. A coated stent has medicine on its outside that slows the regrowth of the artery wall and blocking of the stent. If a coated stent is used, the patient will need to take Plavix for at least two years, perhaps for life.

CORONARY ARTERY BYPASS SURGERY. Coronary artery bypass surgery improves the blood flow to the heart muscle. It is commonly referred to as bypass surgery or coronary artery bypass graft (CABG, pronounced like cabbage) surgery. Bypass surgery is performed to improve blood flow problems to the heart muscle caused by the buildup of plaque in the coronary arteries. The surgery involves using a piece of blood vessel (artery or vein) taken from elsewhere in the body to create a detour or bypass around the blocked portion of the coronary artery. By improving blood flow, bypass surgery may decrease heart-related chest pain, making patients feel better and increasing their ability for physical activity.

In coronary artery bypass surgery, a piece of a healthy blood vessel from the patient's leg, arm, or chest is removed to be used as the bypass. Unless a patient is undergoing one of the newer procedures (minimally invasive bypass or off-pump or beating-heart surgery), the heart is stopped so the surgeons can work on it. A machine called the heart-lung machine takes over the work of the heart and lungs while the surgeon is operating on the heart. The section of healthy blood vessel is attached above and below the blocked artery. When the heart is restarted, blood flow is diverted through the bypass around the narrowed portion of the diseased artery. Depending upon the number of blockages, one to five bypasses may be created.

COUNTER PULSATION. Another medical procedure that can help with CAD is counter pulsation. In this procedure, inflatable cuffs are placed on the legs and lower abdomen. When the heart relaxes, the cuffs inflate and push blood into the blood vessels of the heart. This procedure is repeated over a few days, and it stimulates improved blood flow to the heart. Counter pulsation cannot be performed in people with dilated aortas or who have severe **peripheral vascular disease**.

Lifestyle changes

NUTRITION AND DIET CONCERNS. A healthy diet includes a variety of foods that are low in fat, especially saturated fat and hydrogenated oil; low in cholesterol; and high in fiber. It includes plenty of fruits and vegetables and limits salt. According to the AHA, fats should comprise no more than 25–35% of total daily calories and should total less than 7% saturated fats, less than 1% trans fats, and the remainder as monounsaturated and polyunsaturated fats from such sources as nuts, seeds, fish, and vegetable oils. Cholesterol intake should be limited to 300 mg per day for the average person. Those individuals who have coronary heart disease or who have an LDL cholesterol level of 100 mg/dL or more should lower their daily cholesterol intake to less than 200 mg per day. Eating cold-water fish or taking comparable omega-3 polyunsaturated fatty acid supplements can help prevent cardiac death. The AHA advocates eating fish (particularly fatty fish) at least twice a week. It also recommends adding soybeans (including tofu), canola, walnut, and flaxseed, and their oils to the diet because these contain alpha-linolenic acid than can transform into omega-3 fatty acid in the body. Individuals should consult with their doctor before taking omega-3 fatty acid supplements in excess of 3 g per day because of the potential for bleeding.

Cholesterol, a waxy substance containing fats, is found in foods such as meat, dairy, eggs, and other animal products. It is also produced in the liver. Soluble fiber can help lower cholesterol. Dietary cholesterol should be below 300 mg per day. Many popular lipid-lowering drugs can reduce LDL cholesterol by an average of 25–30% or more when used with a low-fat, low-cholesterol diet.

Antioxidants are chemical compounds in plant foods. When people eat antioxidant-rich foods, they may improve the function of the arteries, prevent arterial plaque formation, and reduce their risk of cancer. Colorful vegetables and fruits are sources of antioxidants and are rich in fiber, **vitamins**, and **minerals**. They are low in calories and nearly fat-free. Vitamin C and beta-carotene, found in many fruits and vegetables, keep LDL-cholesterol from turning into a form that damages coronary arteries. Whole grains, especially whole oats and oat bran, reduce cholesterol.

Excess **sodium** can increase the risk of high blood pressure. Many processed foods contain large amounts of sodium. Daily intake should be limited to about 2,300 mg, about the amount in a teaspoon of salt.

Reports on diet and heart disease have answered some questions, but others remain unclear. While one

WWW.BOOKBAZ.IR

study concludes that four servings per day of fruit and vegetables are associated with a slight drop in risk of heart disease, eight or more servings per day can produce a significant drop in risk. Another study showed that consuming legumes at least four times per week lowered risk of heart disease from 22% to 11% compared with consuming legumes less than once a week. Research on antioxidants continues to produce mixed findings, with some reports showing that vitamins E, C, and other antioxidants can help prevent heart disease and other studies showing they have no effect. Scientists and medical professionals have not reached a consensus about the benefits of antioxidants. As of 2014, the AHA reported that "there isn't sufficient evidence that taking antioxidant supplements will improve your health or reduce your risk of cardiovascular disease." Further, the AHA stated that based on a limited amount of data, scientists have found that antioxidant supplements could actually be harmful. Instead, the organization advised a diet containing a variety of nutrient-rich foods, including fruits, fish, vegetables, high fiber whole grains, and nuts, along with limiting the amount of saturated and trans fats and added sugars.

The Food Guide MyPlate (which supersedes the Pyramid), developed by the Center for Nutrition Policy and Promotion (CNPP), an organization of the U.S. Department of Agriculture (USDA), provides easy-to-follow guidelines for daily heart-healthy eating.

EXERCISING REGULARLY. Regular aerobic exercise can lower blood pressure, help control weight, and increase HDL (good) cholesterol. It also may keep the blood vessels more flexible. The AHA recommends moderate-to-vigorous intensity aerobic activity (50–85% of the maximum heart rate) for at least 30 minutes on most days of the week. Those 30 minutes can be divided into two 15-minute or three 10-minute sessions throughout the day. Aerobic exercise—activities such as walking, jogging, and cycling—uses the large muscle groups and forces the body to use oxygen more efficiently. It also can include everyday activities such as active gardening, climbing stairs, or brisk housework. People with heart disease or risk factors should consult a doctor before beginning an exercise program.

MAINTAINING A DESIRABLE BODY WEIGHT. People who are 20% or more above their ideal body weight have an increased risk of developing heart disease. Losing weight can help decrease total and LDL cholesterol, reduce **triglycerides**, and boost HDL cholesterol. It may also reduce blood pressure. Eating right and exercising are two essential components of losing weight.

QUITTING SMOKING. **Smoking** tobacco products has many adverse effects on the heart. It increases the heart rate, constricts major arteries, and can create irregular heartbeats. It also raises blood pressure, contributes to the development of plaque, increases the formation of blood clots, and causes blood platelets to cluster and impede blood flow. When people quit smoking, heart damage can be repaired. Several studies have shown that ex-smokers face the same risk of heart disease as nonsmokers within five to 10 years after they quit.

DRINKING IN MODERATION. Modest consumption of alcohol may actually protect against heart disease because alcohol appears to raise levels of HDL cholesterol. The AHA defines moderate consumption as one to two daily drinks for men and one daily drink for women, or one ounce of alcohol per day. The association defines one drink as 4 oz. (12 cL) of wine, 12 oz. (35 cL) of beer, 1.5 oz. (4 cL) of 80-proof spirits, or 1 oz. (3 cL) of 100-proof spirits.

SEEKING DIAGNOSIS AND TREATMENT FOR HYPERTENSION. High blood pressure, one of the most common and serious risk factors for heart disease, can be completely controlled through lifestyle changes and medication. Seeking diagnosis and treatment is critical because **hypertension** often exhibits no symptoms, so many people do not know they have it. Moderate hypertension can be controlled by reducing dietary intake of sodium and fat, exercising regularly, managing stress, abstaining from smoking, and drinking alcohol in moderation.

MANAGING STRESS. Everyone experiences stress. Stress can sometimes be avoided, and, when it is inevitable, it can be managed through relaxation techniques, exercise, and other methods.

Alternatives

Herbal-medicine practitioners recommend a variety of remedies that may have a beneficial effect on heart disease. They may suggest garlic (*Allium sativum*), myrrh (*Commiphora molmol*), and oats (*Avena sativa*) to help reduce cholesterol, and hawthorn (*Crataegus* spp.), linden (*Tilia europaea*), and yarrow (*Achillea millefolium*) to control high blood pressure, a risk factor for heart disease. Tea, especially green tea (*Camellia sinensis*), is high in antioxidants, and studies have shown that it may have a preventive effect against atherosclerosis. Coenzyme Q10 (CoQ10) has been shown to be beneficial for patients with congestive heart failure. Taurine, an amino acid found in meat and fish proteins, has also been suggested as a way to treat heart arrhythmia.

Some alternative-medicine practitioners believe that **yoga** and other bodywork, massage, relaxation, **aromatherapy**, and music therapies may help with heart disease and even slow the progression of atherosclerosis. Vitamin and mineral supplements that are believed to reduce, reverse, or protect against heart disease include B-complex vitamins, calcium, chromium, magnesium, L-carnitine, zinc, and the antioxidant vitamins C and E. The Office of Dietary Supplements (ODS), within the National Institutes of Health, state that most intervention trials have not shown that vitamin C lowers risk from cardiovascular disease or reduces the incidence of death from it. However, the ODS does admit that "clinical trial data for vitamin C are limited by the fact that plasma and tissue concentrations of vitamin C are tightly controlled in humans. If subjects' vitamin C levels were already close to saturation at study entry, supplementation would be expected to have made little or no difference on measured outcomes."

Traditional Chinese medicine (TCM) may recommend herbal remedies, massage, **acupuncture**, and dietary modification. A healthy diet (including cold water fish as a source of essential fatty acids) and exercise are important components of both alternative and conventional prevention and treatment strategies.

Prognosis

Advances in medicine and the adoption of healthier lifestyles have caused a substantial decline in death rates from heart disease since the mid-1980s. New diagnostic techniques enable doctors to identify and treat heart disease in its earliest stages. New technologies and surgical procedures have extended the lives of many patients who would have otherwise died. Research continues, and valuable organizations continue to educate clinicians, patients, and healthy individuals alike, in the fight against heart disease.

Prevention

The only way to prevent rheumatic heart disease is to prevent rheumatic fever or successfully treat rheumatic fever before it can damage heart valves. There is no way to prevent congenital heart disease, since it is an inherited (genetic) disorder that develops in the womb.

People can lower their risk of coronary artery disease and heart attack by knowing and controlling their blood pressure, diabetes, and cholesterol. It is also important to lead a healthy lifestyle by not smoking and being physically active (exercising regularly), eating a healthy diet that is lower in fat, especially saturated and trans fat, achieving and maintaining a healthy weight, limiting alcohol use, and reducing stress. Seniors can reduce stress by regularly socializing with friends and family and with such activities as yoga and **meditation**. Many doctors also recommend taking a low-dose (81 mg) of aspirin daily.

A healthy lifestyle can help prevent heart disease and slow its progress. A heart-healthy lifestyle includes maintaining a healthy diet and weight, performing regular exercise, refraining from smoking, engaging in moderate drinking, controlling hypertension, and managing stress. **Cardiac rehabilitation** programs are excellent ways to help prevent recurring coronary problems for people who are at risk and who have had coronary events and procedures.

Caregiver concerns

Patients with heart disease may have as many as five (or more) medications that need to be taken daily. Caregivers should have a system to make sure that the patient takes the medications when and how they are prescribed. Alarms or timers can be used to remind the patient when to take each pill. Also, weekly pill dispensers can help to insure patients only take the dose that is prescribed. Caregivers may want to keep a medicine calendar and note every time the patient takes a dose or have the patient do it. It is vital that the caregiver makes sure that prescriptions are refilled before they run out. Caregivers also need to make sure that their patient is not taking anything that is contraindicated by the condition or that may interact with prescribed medication. Examples include such substances as herbal supplements, **antihistamines**, and **analgesics**. Caregivers need to check with the patient's doctor or pharmacist for possible **drug interactions**. Also, people who take nitrates (such as nitroglycerine) should not take medications for **erectile dysfunction** (ED), including sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis).

Helping patients stick to their diet and exercise routine is critical to their overall health. One way to ensure adherence to a restricted diet is to prepare meals for patients. If this is not feasible, the caregiver can try to limit the amount of forbidden foods that are present in the patient's home. The level of exercise required of patients will depend on their overall health, but for most patients, frequent walks are beneficial. If the caregiver can accompany them on their walks, it will make the experience more enjoyable and increase adherence. Perhaps the most important role of a caregiver is providing emotional support. Simply being there to listen to patients' concerns and to provide encouragement can keep them on the path toward better health. In

WWW.BOOKBAZ.IR

KEY TERMS

Angina—Chest pain.

Angiogram—An x-ray image of one or more blood vessels.

Angioplasty—A surgical operation to clear a narrowed or blocked artery.

Arrhythmia—An irregular heartbeat.

Atherosclerosis—A buildup of plaque in the arteries, also called hardening of the arteries.

Beta-blocker—A drug that blocks some of the effects of fight-or-flight hormone adrenaline (epinephrine and norepinephrine), slowing the heart rate and lowering the blood pressure.

Calcium channel blocker—A drug that blocks the entry of calcium into the muscle cells of small blood vessels (arterioles) and keeps them from narrowing.

Coronary arteries—The main arteries that provide blood to the heart. The coronary arteries surround the heart like a crown, coming out of the aorta, arching down over the top of the heart, and dividing into two branches. These are the arteries in which heart disease occurs.

Echocardiogram—An image of the heart created by ultrasound waves.

Electrocardiogram (ECG or EKG)—A test that measures the electrical activity of the heart.

High-density lipoprotein (HDL) cholesterol—A component of cholesterol that helps protect against heart disease. HDL is described as good cholesterol.

Low-density lipoprotein (LDL) cholesterol—The primary cholesterol molecule. High levels of LDL increase the risk of coronary heart disease. LDL is described as bad cholesterol.

Plaque—A compound made up of fat, cholesterol, calcium, and other substances found in the blood. It can stick to the walls of arteries, partially or totally blocking blood flow.

Triglyceride—A fat that comes from food or is made from other energy sources in the body. Elevated triglyceride levels contribute to the development of atherosclerosis.

Ultrasound—A technique that uses high-frequency sound waves for medical diagnosis and treatment by creating images of internal organs.

Vasodilator—A class of drugs that widen the blood vessels, which in turn decreases resistance to blood flow and lowers blood pressure.

some cases, patients may require at-home **oxygen therapy**. The caregiver should learn how the oxygen equipment is used and make sure more oxygen is ordered well before the current supply runs out.

Heart failure

Definition

Heart failure is a condition in which the heart has lost the ability to pump enough blood to the body's tissues. With too little blood being delivered, the organs and other tissues do not receive enough oxygen and nutrients to function properly.

Description

According to the American Heart Association, about 5 million Americans are living with **congestive heart failure**. Ten of every 1,000 people over age 65 have this condition. There are about 550,000 new cases each year.

Heart failure happens when a disease affects the heart's ability to deliver enough blood to the body's tissues. Often, a person with heart failure may have a buildup of fluid in the tissues, called **edema**. Heart failure with this kind of fluid buildup is called congestive heart failure. Where edema occurs in the body depends on the part of the heart that is affected by heart failure. Heart failure caused by abnormality of the lower left chamber of the heart (left ventricle) means that the left ventricle cannot pump blood out to the body as fast as it returns from the lungs. Because blood cannot get back to the heart, it begins to back up in the blood vessels of the lungs. Some of the fluid in the blood is forced into the breathing space of the lungs, causing **pulmonary edema**. A person with pulmonary edema has **shortness of breath**, which may be acute, severe and life threatening. A person with congestive heart failure feels tired because not enough blood circulates to supply the body's tissues with the oxygen and nutrients they need. Abnormalities of the heart structure and rhythm also can be responsible for left ventricular congestive heart failure.

In right-sided heart failure, the lower right chamber of the heart (right ventricle) cannot pump blood to the lungs as fast as it returns from the body through the veins. Blood then engorges the right side of the heart and the veins. Fluid backed up in the veins is forced out into the tissues, causing swelling (edema), usually in the feet and legs. Congestive heart failure of the right ventricle often is caused by abnormalities of the heart valves and lung disorders.

When the heart cannot pump enough blood, it tries to make up for this by becoming larger. By becoming enlarged (hypertrophic) the ventricle can contract more strongly and pump more blood. When this happens, the heart chamber becomes larger and the muscle in the heart wall becomes thicker. The heart also compensates by pumping more often to improve blood output and circulation. The kidneys try to compensate for a failing heart by retaining more salt and water to increase the volume of blood. This extra fluid also can cause edema. Eventually, as the condition worsens over time these measures are not enough to keep the heart pumping enough blood needed by the body. Kidneys often weaken under these circumstances, further aggravating the situation and making therapy more difficult.

WWW.BOOKBAZ.IR

For most people, heart failure is a chronic disease with no cure. However, it can be managed and treated with medicines and changes in diet, **exercise**, and lifestyle habits. **Heart transplantation** is considered in some cases.

Causes and symptoms

The most common causes of heart failure are:

- coronary artery disease and heart attack (which may be "silent")
- cardiomyopathy
- high blood pressure (hypertension)
- heart valve disease
- congenital heart disease
- alcoholism and drug abuse

The most common cause of heart failure is **coronary artery disease**. In coronary artery disease, the arteries supplying blood to the heart become narrowed or blocked. When blood flow to an area of the heart is completely blocked, the person has a **heart attack**. Some heart attacks go unrecognized. The heart muscle suffers damage when its blood supply is reduced or blocked. If the damage affects the heart's ability to pump blood, heart failure develops.

Cardiomyopathy is a general term for disease of the heart muscle. Cardiomyopathy may be caused by coronary artery disease and various other heart problems. Sometimes the cause of cardiomyopathy cannot be found. In these cases the heart muscle disease is called idiopathic cardiomyopathy. Whatever the cause, cardiomyopathy can weaken the heart, leading to heart failure.

High blood pressure is another common cause of heart failure. High blood pressure makes the heart work harder to pump blood. After a while, the heart cannot keep up and the symptoms of heart failure develop.

Defects of the heart valves, congenital heart diseases, **alcoholism**, and drug abuse cause damage to the heart that can all lead to heart failure.

A person with heart failure may experience the following:

- shortness of breath
- frequent coughing, especially when lying down
- swollen feet, ankles, and legs
- abdominal swelling and pain
- fatigue
- dizziness or fainting
- sudden death

A person with left-sided heart failure may have shortness of breath and coughing caused by the fluid buildup in the lungs. Pulmonary edema may cause the person to **cough** up bubbly phlegm that contains blood. With right-sided heart failure, fluid build-up in the veins and body tissues causes swelling in the feet, legs, and abdomen. When body tissues, such as organs and muscles, do not receive enough oxygen and nutrients they cannot function as well, leading to tiredness and **dizziness**.

Diagnosis

Diagnosis of heart failure is based on:

- symptoms
- medical history
- physical examination
- chest x ray
- electrocardiogram (ECG; also called EKG)
- other imaging tests
- cardiac catheterization

A person's symptoms can provide important clues to the presence of heart failure. Shortness of breath while engaging in activities and episodes of shortness of breath that wake a person from sleep are classic symptoms of heart failure. During the **physical examination**, the physician listens to the heart and lungs with a stethoscope for telltale signs of heart failure. Irregular heart sounds, "gallops," a rapid heart rate, and murmurs of the heart valves may be heard. If there is fluid in the lungs a crackling sound may be heard. Rapid breathing or other changes in breathing may also be present. Patients with heart failure also may have a rapid pulse.

By pressing on the abdomen, the physician can feel if the liver is enlarged. The skin of the fingers and toes may have a bluish tint and feel cool if not enough oxygen is reaching them.

A chest x ray can show if there is fluid in the lungs and if the heart is enlarged. Abnormalities of heart valves and other structures also may be seen on chest x ray.

An electrocardiogram gives information on the heart rhythm and the size of the heart. It can show if the heart chamber is enlarged and if there is damage to the heart muscle from blocked arteries.

Besides chest x ray, other imaging tests may help make a diagnosis. **Echocardiography** uses sound waves to make images of the heart. These images can show if the heart wall or chambers are enlarged and if there are any abnormalities of the heart valves. An

echocardiogram also can be used to find out how much blood the heart is pumping. It determines the amount of blood in the ventricle (ventricular volume) and the amount of blood the ventricle pumps each time it beats (called the ejection fraction). A healthy heart pumps at least one-half the amount of blood in the left ventricle with each heartbeat. Radionuclide ventriculography also measures the ejection fraction by imaging with very low doses of an injected radioactive substance as it travels through the heart.

A new test that measures the level of a particular hormone in the blood was introduced in 2003 and researchers said the test may be useful for testing for heart failure in physicians' offices because it could provide results in 15 minutes.

Cardiac catheterization involves using a small tube (catheter) that is inserted through a blood vessel into the heart. It is used to measure pressure in the heart and the amount of blood pumped by the heart. This test can help find abnormalities of the coronary arteries, heart valves, and heart muscle, and other blood vessels. Combined with echocardiography and other tests, cardiac catheterization can help find the cause of heart failure. It is not always necessary, however.

Treatment

Heart failure usually is treated with lifestyle changes and medicines. Sometimes surgery is needed to correct abnormalities of the heart or heart valves. Heart transplantation is a last resort to be considered in certain cases.

Dietary changes to maintain proper weight and reduce salt intake may be needed. Reducing salt intake helps to lessen swelling in the legs, feet, and abdomen. Appropriate exercise also may be recommended, but it is important that heart failure patients only begin an exercise program with the advice of their doctors. Walking, bicycling, swimming, or low-impact aerobic exercises may be recommended. There are good heart **rehabilitation** programs at most large hospitals.

Other lifestyle changes that may reduce the symptoms of heart failure include stopping **smoking** or other tobacco use, eliminating or reducing alcohol consumption, and not using harmful drugs.

One or more of the following types of medicines may be prescribed for heart failure:

- diuretics
- digitalis
- vasodilators
- beta blockers
- angiotensin converting enzyme inhibitors (ACE inhibitors)
- angiotensin II receptor blockers (ARBs)
- calcium channel blockers
- blood thinners
- potassium

Diuretics help eliminate excess salt and water from the kidneys by making patients urinate more often. This helps reduce the swelling caused by fluid buildup in the tissues. Digitalis helps the heart muscle to have stronger pumping action. **Vasodilators**, ACE inhibitors, ARBs, and **calcium channel blockers** lower blood pressure and expand the blood vessels so blood can move more easily through them. This action makes it easier for the heart to pump blood through the vessels. Cholesterol-lowering drugs called statins can help prevent death from heart failure. A 2003 study showed a 62% drop in the mortality rate among patients with severe heart failure who took statin therapy.

In 2005, the U.S. Food and Drug Administration (FDA) approved a new noninvasive procedure for patients with congestive heart failure. Called **enhanced external counterpulsation** (EECP), it consists of inflating three sets of pneumatic cuffs attached to the patient's legs. The therapy had positive effects on the blood pressure and reduced frequency of episodes of **angina** (pain) in a clinical trial by as much as 70%.

Surgery is used to correct certain heart conditions that cause heart failure. Congenital heart defects and abnormal heart valves can be repaired with surgery. Blocked coronary arteries usually can be treated with **angioplasty** or coronary artery bypass surgery.

With severe heart failure, the heart muscle may become so damaged that available treatments do not help. Patients with this stage of heart failure are said to have end-stage heart failure. Heart transplant usually is considered for patients with end-stage heart failure when all other treatments have stopped working.

Prognosis

Most patients with mild or moderate heart failure can be successfully treated with dietary and exercise programs and the right medications. Even those awaiting heart transplants could benefit from exercise. Many people are able to participate in normal daily activities and lead relatively active lives.

Patients with severe heart failure may eventually have to consider heart transplantation. Approximately 50% of patients diagnosed with congestive

WWW.BOOKBAZ.IR

KEY TERMS

Angioplasty—A technique for treating blocked coronary arteries by inserting a catheter with a tiny balloon at the tip into the artery and inflating it.

Angiotensin-converting enzyme (ACE) inhibitor—A drug that relaxes blood vessel walls and lowers blood pressure.

Arrhythmias—Abnormal heartbeat.

Atherosclerosis—Buildup of a fatty substance called a plaque inside blood vessels.

Calcium channel blocker—A drug that relaxes blood vessels and lowers blood pressure.

Cardiac catheterization—A diagnostic test for evaluating heart disease; a catheter is inserted into an artery and passed into the heart.

Cardiomyopathy—Disease of the heart muscle.

Catheter—A thin, hollow tube.

Congenital heart defects—Abnormal formation of structures of the heart or of its major blood vessels present at birth.

Congestive heart failure—A condition in which the heart cannot pump enough blood to supply the body's tissues with sufficient oxygen and nutrients; back up of blood in vessels and the lungs causes buildup of fluid (congestion) in the tissues.

Coronary arteries—Arteries that supply blood to the heart muscle.

Coronary artery bypass—Surgical procedure to reroute blood around a blocked coronary artery.

Coronary artery disease—Narrowing or blockage of coronary arteries by atherosclerosis.

Digitalis—A drug that helps the heart muscle to have stronger pumping action.

Diuretic—A type of drug that helps the kidneys eliminate excess salt and water.

Edema—Swelling caused by fluid buildup in tissues.

Ejection fraction—A measure of the portion of blood that is pumped out of a filled ventricle.

Heart valves—Valves that regulate blood flow into and out of the heart chambers.

Hypertension—High blood pressure.

Hypertrophic—Enlarged.

Idiopathic cardiomyopathy—Cardiomyopathy without a known cause.

Pulmonary edema—Buildup of fluid in the tissue of the lungs.

Vasodilator—Any drug that relaxes blood vessel walls.

Ventricles—The two lower chambers of the heart.

heart failure live for five years with the condition. Women with heart failure usually live longer than men with heart failure.

Prevention

Heart failure usually is caused by the effects of some type of **heart disease**. The best way to try to prevent heart failure is to eat a healthy diet and get regular exercise, but many causes of heart failure cannot be prevented. People with risk factors for coronary disease (such as high blood pressure and high **cholesterol** levels) should work closely with their physician to reduce likelihood of heart attack and heart failure.

Heart failure sometimes can be avoided by identifying and treating any conditions that might lead to heart disease. These include high blood pressure, alcoholism, and coronary artery disease. Regular blood pressure checks and obtaining immediate medical care for symptoms of coronary artery disease, such as chest pain, will help to get these conditions diagnosed and treated early, before they can damage the heart muscle.

A 2003 initiative called OPTIMIZE H-F was aimed at preventing severe heart failure and deaths among patients discharge from hospitals. The project created a registry or database of patients with heart failure that could be shared among hospitals. Finally, diagnosing and treating heart failure before the heart becomes severely damaged can improve the prognosis. With proper treatment, many patients may continue to lead active lives for a number of years.

Heart murmurs

Definition

A heart murmur is an abnormal or extra sound heard during the heartbeat cycle. Some murmurs are made by blood moving unevenly through healthy valves in a healthy heart. Such murmurs are normal and are not a medical concern. Other murmurs are produced by blood moving roughly (turbulently) through damaged or overworked heart valves. These murmurs are not normal and can be a serious health problem. Both are detected by the physician's examination using a stethoscope and may sound like a swishing, blowing, rasping, or whooshing noise. The noise may range from very faint to quite loud.

Description

Heart murmurs can be of two types: those that are normal, what are called innocent or harmless murmurs, and other ones that are potentially harmful to the health of a person with one, what are called abnormal or pathologic murmurs. Some heart murmurs are congenital (present at birth), whereas others develop later in life. In adults, most abnormal heart murmurs are caused by infections, other diseases, or **aging**. Heart murmurs are also divided according to when they occur. They are diastolic murmurs when made during the relaxation part of a beating heart or systolic murmurs when occurring during the contraction of the heart. Other classifications are also used by the medical community to describe heart murmurs.

A heart that is beating normally makes two sounds: "lubb," which is heard when the valves between the atria and ventricles close; and "dupp," which is heard when the valves between the ventricles and the major arteries close. The first sound (lubb) is known as S1 in medical shorthand, and the second heart sound (dupp or dub) is known as S2. A heart murmur is a series of vibratory sounds made by turbulent blood flow. The sounds are longer than normal heart sounds and can be heard between the normal sounds of the heart. Murmurs can happen for numerous reasons, but most often they occur when a valve does not close tightly, and blood blows backwards (what is called regurgitation) or when blood blows through a stiff or narrowed valve (what is termed stenosis).

Heart murmurs are common in children and can also result from heart or valve defects. Nearly two-thirds of heart murmurs in children are produced by normal hearts and are harmless. This type of heart murmur, called innocent heart murmur, can also be called a functional murmur, flow murmur, or physiologic heart murmur, among others. Innocent heart murmurs are usually very faint, intermittent, and occur in a small area of the chest. Women may develop innocent heart murmurs during **pregnancy** because extra blood flows through the heart to provide nutrients to both her body and her fetus's body.

Pathologic heart murmurs may indicate the presence of a serious heart defect. They are louder,

WWW.BOOKBAZ.IR

continual, and may be accompanied by a click or gallop. In children, abnormal heart murmurs are often the result of congenital heart defects. The structure of the heart has not developed properly, causing a defect in the heart, which can lead to murmurs and other problems. In adults, heart murmurs can be the result of diseases of the heart muscle (such as **hypertrophic cardiomyopathy**), heart valve problems (sometimes called acquired heart valve disease), and septal defects (holes in the heart).

For instance, **mitral valve prolapse** occurs when the mitral valve does not close properly when the left ventricle contracts. Specifically, the valve extends outward abnormally, which stops the blood from flowing into the left atrium. When this happens, a clicking sound is produced, which is a sign of a particular type of heart murmur.

In another example, aortic sclerosis is caused by scarring or stiffening (sclerosis) of the aortic valve. This problem with the valve is often brought on with age. It can produce a heart murmur in some people.

Some heart murmurs are continually present; others occur only when the heart is working harder than usual, including during **exercise** or certain types of illness. Heart murmurs can be diastolic or systolic. Those that occur during relaxation of the heart between beats are called diastolic murmurs. Those that occur during contraction of the heart muscle are called systolic murmurs. Murmurs that can be heard throughout the heartbeat cycle are called continuous murmurs. The characteristics of the murmur may suggest specific alterations in the heart or its valves.

Heart murmurs are evaluated according to several characteristics:

- Timing. Timing refers to whether the murmur is systolic, diastolic, or continuous.
- Shape. Shape refers to the loudness of the murmur over time. Some grow louder (crescendo); some grow softer (decrescendo); and some grow louder and then softer (crescendo/decrescendo).
- Location. This characteristic refers to the place on the front of the chest where the doctor can best hear the murmur.
- Radiation. Radiation refers to the direction of the movement of the sound of the murmur. In general, heart murmurs radiate in the direction of the blood flow.
- Intensity. Intensity refers to the loudness of the murmur and is graded on a scale of 1 to 6. A grade 1 murmur is difficult to hear; grade 3 can be heard all over the portion of the chest over the heart; grade 5 can be heard with the stethoscope partly off the chest; and grade 6 is loud enough to be heard with the stethoscope completely off the chest. An example of a grade is "grade III/VI murmur," which means it is a grade 3 on a scale of 1 to 6.
- Pitch. The pitch of a murmur can be low, medium, or high.
- Quality. This characteristic refers to unusual aspects of the murmur's sound. Some murmurs can be described as harsh, rumbling, blowing, or even musical.

Risk factors

Risk factors for heart murmurs in an unborn child include:

- family history of heart murmurs or heart defects
- illnesses during pregnancy, particularly poorly controlled diabetes and rubella (German measles)
- using alcohol or illegal drugs during pregnancy

Risk factors for abnormal heart murmurs in adults include:

- anemia
- fever
- high blood pressure
- overactive thyroid
- pregnancy

According to the National Heart, Lung and Blood Institute, there are no known risk factors for innocent heart murmurs in the general population.

Demographics

Innocent (harmless) heart murmurs are quite common in the general population, for both children and adults. According to the Lippincott's Nursing Center, heart murmurs in newborn babies occur in 0.6–4.2% of the population. About 90% of infants and children have a heart murmur at some point in their young lives. Less than 1% of childhood murmurs are caused by a congenital heart defect. Most heart murmurs in children, both harmless and harmful ones, are without symptoms. In adults, approximately twice as many women have heart murmurs as do men.

Causes and symptoms

Heart murmurs in general are caused by the turbulence of blood flowing through the chambers and valves of the heart or the blood vessels near the heart strongly enough to produce audible sounds. Sometimes **anxiety**, **stress**, **fever**, anemia, an overactive thyroid gland, and

pregnancy will cause innocent murmurs that can be heard by a physician using a stethoscope. Some of the more common innocent heart murmurs in children are called pulmonary flow murmurs, still's murmurs, and venous hum. In general, innocent heart murmurs are not caused by heart problems.

Pathologic heart murmurs are caused by structural abnormalities of the heart. These include defective heart valves or holes in the walls of the heart. Valve problems are more common. Valves that do not open completely cause blood to flow through a smaller opening than normal, whereas those that do not close properly may cause blood to go back through the valve. A hole in the wall between the left and right sides of the heart, called a septal defect, can cause heart murmurs. Some septal defects close on their own, whereas others require surgery to prevent progressive damage to the heart. According to MedlinePlus, a service of the National Library of Medicine and the National Institutes of Health, some of the medical causes of abnormal heart murmurs are as follows:

- aortic regurgitation
- aortic stenosis
- hypertrophic cardiomyopathy
- acute or chronic mitral regurgitation
- mitral stenosis
- pulmonary stenosis
- tricuspid regurgitation
- tricuspid stenosis

Most abnormal heart murmurs in children are caused by congenital heart defects, whereas such murmurs in adults are usually the result of heart valve disease. In children, the most common abnormal heart murmurs as a result of medical conditions are:

- anomalous pulmonary venous return
- atrial septal defect
- coarctation of the aorta
- patent ductus arteriosus
- ventricular septal defect

The symptoms of heart murmurs differ depending on the cause of the heart murmur. Innocent heart murmurs and those that do not impair the function of the heart have no symptoms, other than the murmur itself. Murmurs that are due to severe abnormalities of a heart valve may cause:

- shortness of breath, which may only occur during physical exertion
- dizziness
- chest pains
- faintness
- a bluish discoloration of the skin of the fingertips and lips
- swollen veins in the neck
- chronic coughing
- enlarged liver
- larger than normal veins in the neck
- heavy sweating with little or no exertion
- palpitations
- lung congestion
- in infants, failure to grow physically, along with poor eating habits

Diagnosis

The diagnosis of a heart murmur begins with taking a careful patient history. The doctor may ask about a family history of heart murmurs or **heart disease**. The doctor may also ask about symptoms that may be associated with heart disorders, such as **fainting**, chest **pain**, a bluish tinge to the complexion, **shortness of breath**, weight gain, and swelling. The doctor will also check the size of the patient's liver by feeling the abdomen and look for swollen neck veins.

In serious cases of heart murmur a primary care physician may refer the patient to a specialist, such as a cardiologist for adults or a pediatric cardiologist for children. The family doctor or a specialist may order a chest x ray if an abnormal heart murmur is suspected. An electrocardiogram or an echocardiograph may also be recommended. These tests help to identify problems with the heart, including the reason why the heart murmur is present.

Examination

Heart murmurs can be heard during an office examination when a pediatrician or primary care physician listens to the heart through a stethoscope during a regular checkup. The doctor's listening to heart or other body sounds is called auscultation. After listening to the heart sounds, the doctor will also check for any unusual sounds in the lungs. Very loud heart murmurs and those with clicks or extra heart sounds should be evaluated further. The doctor may ask the patient to stand, squat, hold the breath while bearing down, or squeeze an object in the hand during auscultation. These maneuvers help the doctor to evaluate the location and possible cause of the murmur.

Infants with heart murmurs who do not thrive, eat, or breathe properly, and older children who lose consciousness suddenly or are intolerant of exercise

WWW.BOOKBAZ.IR

should also be evaluated. If the murmur sounds suspicious, the physician may order a chest x ray, an electrocardiogram, and an echocardiogram. A primary care physician may refer the patient to a cardiologist, who is a doctor who specializes in diagnosing and treating heart disorders.

Tests

An electrocardiogram (ECG) displays the heart's activity and may reveal muscle thickening, damage, or a lack of oxygen. Electrodes covered with conducting jelly are placed on the patient's chest, arms, and legs. They send impulses of the heart's activity through a monitor (oscilloscope) to a recorder that traces them on paper. The test takes about 10 minutes and is commonly performed in a physician's office. An exercise ECG can reveal additional information.

An echocardiogram (cardiac **ultrasound**) may be ordered to identify a structural problem that is causing the heart murmur. An echocardiogram uses sound waves to create an image of the heart's chambers and valves. The technician applies gel to a hand-held transducer then presses it against the patient's chest. The sound waves are converted into an image that can be displayed on a monitor. Performed in a cardiology outpatient diagnostic laboratory, the test takes 30 minutes to an hour.

In some cases the doctor may administer a drug to further evaluate a murmur. The two compounds used most often for such tests are amyl nitrite, which expands blood vessels and lowers blood pressure, and methoxamine, which has the opposite effect, namely constricting blood vessels and raising blood pressure.

Procedures

In some cases the doctor may recommend **cardiac catheterization** to evaluate the condition of the patient's heart. This procedure involves the use of x-ray and ultrasound imaging to guide a long thin tube called a catheter through a major blood vessel into the heart. The doctor can inject a dye visible on x-ray images through the catheter and trace its flow through the chambers of the heart in order to identify problems in the valves or other structures of the heart.

Treatment

Many heart murmurs do not need treatment. However, if the murmur is caused by a heart problem or other medical condition, then treatment may be necessary.

Traditional

Innocent heart murmurs do not affect the patient's health and require no treatment. Treatment when needed is directed toward the cause of the heart murmur. Heart murmurs due to septal defects may require surgery. Those due to valvular defects may require **antibiotics** to prevent infection during certain surgical or dental procedures. Severely damaged or diseased valves can be repaired or replaced through surgery. A medical condition that is causing the murmur is often treated to remove the murmur. For instance if the condition is anemia or **hyperthyroidism**, then once these are treated successfully, the murmur should go away, too.

Drugs

Some heart murmurs can be managed with various medications. Depending on the specific cause of the murmur, the doctor might prescribe one or more of the following types of drugs:

- Diuretics. Diuretics, sometimes called water pills, remove fluid from the blood by increasing urinary output. They can be used to lower blood pressure, as high blood pressure can worsen a heart murmur.
- Angiotensin-converting enzyme (ACE) inhibitors. These are another class of drugs often prescribed to lower high blood pressure.
- Statins. Statins are a group of drugs given to control blood cholesterol levels. High blood cholesterol is a risk factor for making some heart valve problems worse.
- Digoxin (Lanoxin). Also known as digitalis, digoxin is a drug that increases the strength of the heart muscle's contractions, making the heart pump blood more efficiently.
- Aspirin or other anticoagulants. Anticoagulants, sometimes called blood thinners, are drugs that prevent blood clots from forming in the heart, thus lowering the risk of a stroke or heart attack.

Alternatives

There are no alternative treatments for heart murmurs that require surgical treatment, although there are alternative therapies that are helpful for pre- and post-surgical support of the patient. If the heart murmur is innocent, heart activity can be supported using the herb hawthorn (*Crataegus laevigata* or *C. oxyacantha*) or coenzyme Q10 (CoQ10). These remedies improve heart contractility and the heart's ability to use oxygen. If the murmur is valvular in origin, herbs that act like antibiotics as well as options that build resistance to infection in the valve areas may be considered.

KEY TERMS

Atria (singular, atrium)—The upper two chambers of the heart.

Auscultation—The medical term for listening to the sounds of the heart or other body organs.

Cardiologist—A doctor who specializes in diagnosing and treating disorders of the heart.

Congenital—Present at birth.

Echocardiogram—A noninvasive ultrasound test that shows an image of the inside of the heart. It can be performed to identify any structural problems that cause a heart murmur.

Electrocardiogram—A test that shows the electrical activity of the heart by placing electronic sensors on the patient. This test can be used to confirm the presence of a heart murmur.

Innocent—The medical term for a harmless condition.

Pathologic—Characterized by disease or the structural and functional changes due to disease. Pathologic heart murmurs may indicate a heart defect.

Ventricles—The lower two chambers of the heart.

Prognosis

The prognosis of a heart murmur depends on its cause, along with its severity. Most children with innocent heart murmurs grow out of them by the time they reach adulthood. Serious causes of heart murmurs may progress to severe symptoms and even death.

Prevention

Apart from keeping diabetes under control and avoiding drug or alcohol abuse during pregnancy, there is no known way to prevent heart murmurs.

Heart surgery for congenital defects

Definition

Heart surgery for congenital defects consists of a variety of surgical procedures performed to repair the many types of heart defects that may be present at birth and may remain undiagnosed into adulthood.

WWW.BOOKBAZ.IR

Purpose

Heart surgery for congenital defects is performed to repair a defect, providing improved blood flow to the pulmonary and systemic circulations and better oxygen delivery to the body. Congenital heart defects that are symptomatic at birth must be treated with palliative or complete surgical repair. Defects that are not symptomatic at birth may be discovered later in life, and will be treated to relieve symptoms by palliative or complete surgical repair. Surgery is recommended for congenital heart defects that result in a lack of oxygen, poor quality of life, or **failure to thrive**. Even lesions that are asymptomatic may be treated surgically to avoid additional complications later in life.

Demographics

Congenital heart disease is estimated to involve less than 1% of all live births. As some defects are not found until later in life, or may never be diagnosed, this number may actually be higher. Many congenital defects are often incompatible with life, leading to **miscarriage** and stillbirths. During a child's first year of life, the most common defects that are symptomatic include **ventricular septal defect** (VSD), transposition of the great vessels (TGV), **tetralogy of Fallot**, **coarctation of the aorta**, and hypoplastic left heart syndrome. Premature infants have an increased likelihood of VSD and **patent ductus arteriosus**. Diabetic mothers have infants with a higher incidence of congenital heart defects than non-diabetic mothers. Abnormal chromosomes increase the incidence of congenital heart defects; for example, infants with **Down syndrome** have a 23–56% chance of being born with a heart defect.

Description

Pediatric cardiologists and cardiac surgeons specialize in the treatment of congenital defects. Hospitals dedicated to the care of children may provide cardiac surgery services. Congenital defects diagnosed at birth may require immediate transport of the infant to a facility that can provide timely treatment.

Congenital heart defects can be named according to a number of specific lesions, but may also involve additional lesions. Classification best describes lesions by the amount of pulmonary blood flow (increased or decreased) or the presence of an obstruction to blood flow. The dynamic circulation of the newborn as well as the size of the defect will determine the symptoms. Recommended ages for surgery for the most common congenital heart defects are:

- atrial septal defects: during the preschool years
- patent ductus arteriosus: between ages 1 and 2
- coarctation of the aorta: in infancy if it is symptomatic, at age 4 otherwise
- tetralogy of Fallot: age varies according to the patient's symptoms
- transposition of the great arteries: often in the first weeks after birth; otherwise, before the patient is 12 months old

Surgical procedures seek to repair the defect and restore normal pulmonary and systemic circulation. Sometimes multiple serial surgical procedures are necessary.

Many congenital defects are often associated so that the surgical procedures described may be combined for complete repair of a specific congenital defect.

Repair for simple cardiac lesions can be performed in the **cardiac catheterization** lab. Catheterization procedures include balloon atrial septostomy and **balloon valvuloplasty**. Surgical procedures include arterial switch, Damus-Kaye-Stansel procedure, Fontan procedure, Ross procedure, shunt procedure, and venous switch or intra-atrial baffle.

Catheterization procedures

Balloon atrial septostomy and balloon valvuloplasty are cardiac catheterization procedures. Cardiac catheterization procedures can save the lives of critically ill newborns and, in some cases, eliminate or delay more invasive surgical procedures. It is expected that catheterization procedures will continue to replace more types of surgery for congenital heart defects in the future. A thin tube called a catheter is inserted into an artery or vein in the leg, groin, or arm and threaded into the area of the heart that needs repair. The patient receives a local anesthetic at the insertion site. General anesthetic or **sedation** may be used.

BALLOON ATRIAL SEPTOSTOMY. Balloon atrial septostomy is the standard procedure for correcting **transposition of the great arteries**; it is sometimes used in patients with mitral, pulmonary, or tricuspid atresia. (Atresia is the lack of or poor development of a structure.) Balloon atrial septostomy enlarges the atrial septal opening, which normally closes in the days following birth. A special balloon-tipped catheter is inserted into the right atrium and passed into the left atrium. The balloon is inflated in the left atrium and pulled back across the septum to create a larger opening in the atrial septum.

KEY TERMS

Atresia—Lack of development. In tricuspid atresia, the tricuspid valve has not developed. In pulmonary atresia, the pulmonary valve has not developed.

Coarctation of the aorta—A congenital defect in which severe narrowing or constriction of the aorta obstructs the flow of blood.

Congenital heart defects—Heart defects that are present at birth.

Mitral valve—The heart valve connecting the left atrium and the left ventricle.

Patent ductus arteriosus—A congenital defect in which the temporary blood vessel connecting the left pulmonary artery to the aorta in the fetus fails to close in the newborn.

Pulmonary valve—The heart valve connecting the left atrium and the pulmonary arteries.

Septal defects—Openings in the septum, the muscular wall separating the right and left sides of the heart. Atrial septal defects are openings between the two upper heart chambers and ventricular septal defects are openings between the two lower heart chambers.

Stenosis—Narrowing of the heart's valves.

Tetralogy of Fallot—A defect in which the blood pumped through the body has too little oxygen. Tetralogy of Fallot includes four defects: a ventricular septal defect, narrowing at or beneath the pulmonary valve, infundibular pulmonary stenosis (obstruction of blood flow from the right ventricle through the pulmonary valve), and overriding aorta (the aorta crosses the ventricular septal defect into the right ventricle).

Transposition of the great vessels—A cyanotic defect in which the blood pumped through the body has too little oxygen because the pulmonary artery receives its blood incorrectly from the left ventricle and the aorta incorrectly receives blood flow from the right ventricle.

Tricuspid valve—The heart valve connecting the right atrium and right ventricle.

BALLOON VALVULOPLASTY. Balloon valvuloplasty uses a balloon-tipped catheter to open a stenotic (narrowed) heart valve, improving the flow of blood through the valve. It is the procedure of choice in pulmonary stenosis and is sometimes used in aortic and mitral stenosis. A balloon is placed beyond the valve, inflated, and pulled backward across the valve.

Surgical procedures

Surgical procedures are performed under general **anesthesia**. Some require the use of a heart-lung machine, which takes over for the heart and lungs during the procedure, providing cardiopulmonary bypass. The heart-lung machine can cool the body to reduce the need for oxygen, allowing deep hypothermic circulatory arrest (DHCA) to be performed. DHCA benefits the surgeon by creating a bloodless surgical field.

ARTERIAL SWITCH. Arterial switch is performed to correct transposition of the great vessels, in which the position of the pulmonary artery and the aorta are reversed. The procedure involves connecting the aorta to the left ventricle and the pulmonary artery to the right ventricle.

DAMUS-KAYE-STANSEL PROCEDURE. Transposition of the great vessels can also be corrected by the Damus-Kaye-Stansel procedure, in which the pulmonary artery is cut in two and connected to the ascending aorta and right ventricle.

VENOUS SWITCH. For transposition of the great vessels, venous switch creates a tunnel inside the atria to redirect oxygen-rich blood to the right ventricle and aorta and venous blood to the left ventricle and pulmonary artery. This procedure differs from the arterial switch and Damus-Kaye-Stansel procedures in that blood flow is redirected through the heart.

FONTAN PROCEDURE. For tricuspid atresia and pulmonary atresia, the Fontan procedure connects the right atrium to the pulmonary artery directly or with a conduit, and the **atrial septal defect** is closed.

PULMONARY ARTERY BANDING. Pulmonary artery banding is narrowing the pulmonary artery with a band to reduce blood flow and pressure in the lungs. It is used for temporary repair of ventricular septal defect, atrioventricular canal defect, and tricuspid atresia. Later, the band can be removed and the defect corrected with a complete repair once the patient has grown.

ROSS PROCEDURE. To correct aortic stenosis, the Ross procedure grafts the pulmonary artery to the aorta.

SHUNT PROCEDURE. For tetralogy of Fallot, tricuspid atresia, or pulmonary atresia, the shunt procedure

WWW.BOOKBAZ.IR

creates a passage between blood vessels, directing blood flow into the pulmonary or systemic circulations.

OTHER TYPES OF SURGERY. Surgical procedures are also used to treat common congenital heart defects. To close a medium-to-large ventricular or atrial septal defect, it is recommended that it be sutured or covered with a Dacron patch. For patent ductus arteriosus, surgery consists of dividing the ductus in two and tying off the ends. If performed within the child's first few years, there is practically no risk associated with this operation. Surgery for coarctation of the aorta involves opening the chest wall, removing the defect, and reconnecting the ends of the aorta. If the defect is too long to be reconnected, a Dacron graft is used to replace the missing piece.

Preparation

Before surgery for congenital heart defects, the patient will receive a complete evaluation, which includes a physical exam, a detailed family history, a **chest x ray**, an electrocardiogram, an echocardiogram, and usually cardiac catheterization. Blood tests will be performed to measure formed blood elements, electrolytes, and blood glucose. Additional tests for sickle cell hemoglobin and **digoxin** levels may be performed when applicable. For six to eight hours before the surgery, the patient cannot eat or drink anything.

Aftercare

After heart surgery for congenital defects, the patient goes to an intensive care unit for continued cardiac monitoring. The patient may also require continued ventilator support. Chest tubes allow blood to be drained from inside the chest as the surgical site heals. **Pain** medications will be continued, and the patient may remain under general anesthetic. Within 24 hours, the chest tubes and ventilation may be discontinued. Any cardiac drugs used to help the heart perform better will be adjusted to a level appropriate with the patient's condition.

For temporary procedures, additional follow-up with the physician will be required to judge timing for complete repair. In the meantime, the patient should continue to grow and thrive normally. Complete repair requires follow-up with the physician initially to judge the adequacy of repair, but thereafter will be infrequent with good prognosis. The child should be made aware of any procedures performed, so that this information can be communicated to medical personnel for future medical care in adulthood.

Risks

Depending on the institution and the type of congenital defect repair, many risks can be identified, including **shock**, **congestive heart failure**, lack of oxygen or too much carbon dioxide in the blood, irregular heartbeat, **stroke**, infection, kidney damage, lung blood clot, low blood pressure, hemorrhage, cardiac arrest, and death. These risks should not impede the surgical procedure, as death is certain without surgical treatment. Neurological dysfunction in the postoperative period occurs in as much as 25% of surgical patients. Seizures are expected in 20% of cases, but are usually limited with no long-term effects. Additional risks include blood **transfusion** reactions and bloodborne pathogens.

Morbidity and mortality rates

Use of cardiopulmonary bypass has associated risks not related to the congenital defect repair. Procedures performed in association with cardiac catheterization have excellent long-term results, with an associated mortality of 2–4% of procedures. The Fontan procedure carries a survival rate of over 90%. Surgical procedures to repair coarctation of the aorta in uncomplicated cases have a risk of operative mortality from 1–2%.

Alternatives

Alternatives are limited for this patient population. Cardiac transplant is an option, but a limited number of organ donors restrict this treatment. Ventricular-assist devices and total artificial heart technology are not yet suitable options. Temporary procedures do allow patients to grow prior to corrective surgery, allowing them to gain strength and size before treatment.

Heart transplantation

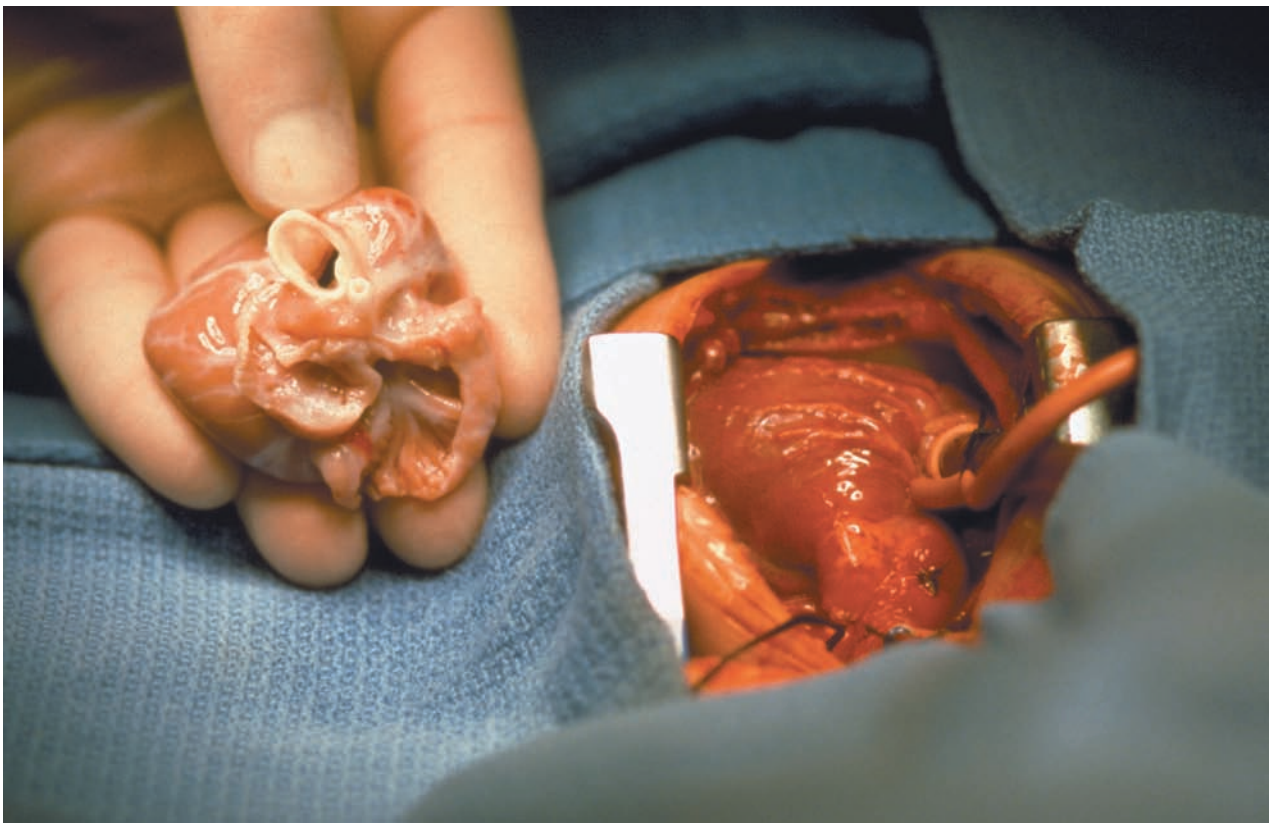
Definition

Heart transplantation, also called cardiac transplantation, is the replacement of a patient's diseased or injured heart with a healthy donor heart. This type of transplant is called an allograft because it involves the transplantation of an organ from a genetically non-identical donor of the same species (in this case, human) as the recipient.

Purpose

Heart transplantation is performed on patients with end-stage **heart failure** or some other life-threatening **heart disease**. Before a doctor recommends heart transplantation for a patient, all other possible treatments for his or her disease must have been attempted. The purpose of heart transplantation is to extend and improve the life of a person who would otherwise die from heart failure. Most patients who receive a new heart are so sick before transplantation that they cannot live a normal life. Replacing a patient's diseased heart with a healthy, functioning donor heart often allows the recipient to return to normal daily activities.

WWW.BOOKBAZ.IR



A comparison of the old and new hearts of Dylan Stork. At the time, he was the smallest heart transplant recipient in the world. Dylan was seven weeks old and weighed 5.5 lb. (2.5 kg) at the time of the operation. *(Alexander Tsiaras/Photo Researchers, Inc.)*

Demographics

Heart transplant recipients are not limited by sex, race, or ethnicity. Nevertheless, because healthy donor hearts are in short supply, strict rules dictate criteria for heart transplant recipients. Patients who may be too sick to survive the surgery or the side effects of immunosuppressive therapy would not be good transplant candidates. Age is also a factor; patients over the age of 70 are not usually considered for heart transplantation.

In 2011 (the last year for which data were available), 2,322 heart transplants were performed in the United States according to the Organ Procurement and Transplantation Network. Of these, people between the ages of 50 and 64 were most likely to receive a heart transplant, while children ages 6–10 were least likely to have heart transplantation surgery. In 2011, men received 69% of transplants while women received 31%. Caucasians received 66% of transplants, African Americans 21%, Hispanics 9%, and Asian Americans 3%. The primary diagnoses of adult patients receiving heart transplantation include **coronary artery disease**, **cardiomyopathy**, congenital heart diseases, and retransplantation associated with organ rejection.

These conditions are contraindications for heart transplantation:

- active infection
- pulmonary hypertension
- chronic lung disease with loss of more than 40% of lung function
- untreatable liver or kidney disease
- diabetes that has caused serious damage to vital organs
- disease of the blood vessels in the brain, such as a stroke
- serious disease of the arteries
- mental illness or any condition that would make a patient unable to take the necessary drugs and treatments on schedule
- ongoing alcohol or drug abuse

National transplant waiting list by organ type (September 2014)

Organ needed	Persons waiting
Kidney	101,116
Liver	15,679
Heart	4,016
Kidney/Pancreas	4,016
Lung	1,614
Pancreas	1,182
Intestine	259
Heart/Lung	53

(Table by PreMediaGlobal. © Cengage Learning®.)

Description

Patients with end-stage heart disease unresponsive to medical treatment may be considered for heart transplantation. Potential candidates must have a complete medical examination before they can be put on the transplant waiting list. Many types of tests are done, including blood tests, x rays, and tests of heart, lung, and other organ function. The results of these tests indicate to doctors how serious the heart disease is and whether the patient is healthy enough to survive the **transplant surgery**.

Patients are evaluated for heart transplantation by a team that includes a cardiologist, cardiac surgeon, transplant coordinator, dietitian, social worker, and psychiatrist. The cardiac surgeon, anesthesiologist, and surgical team with additional training in transplant surgery will perform the operation. Postoperative care is given by nurses, respiratory therapists, physical therapists, and occupational therapists. Patients who develop **anxiety disorders** or depression after transplantation may be treated by a psychotherapist.

Organ waiting list

A person approved for heart transplantation is placed on the heart transplant waiting list. Patients requesting a heart transplant must be under age 69 at the time they join the list; once on the list they may remain on it past that age. All patients on the waiting list are registered with the United Network for Organ Sharing (UNOS). UNOS has organ transplant specialists who run a national computer network that connects all the transplant centers and organ-donation organizations. Patients are grouped in terms of priority based on how long they can live without a transplant. The list is national and independent of the heart transplant center where the surgery will take place.

The need for donated hearts outweighs the supply. At any given time, about 3,500 to 4,000 people are waiting for hearts, while only about 2,200 hearts are available each year. When a donor heart becomes available, information about the donor heart is entered into the UNOS computer and compared to information about patients on the waiting list. The computer program produces a list of patients ranked according to blood type, size of the heart, and how urgently they need a heart. Because the heart must be transplanted as quickly as possible, a list of local patients is checked first for a good match. After that, a regional list and then a national list are checked. The patient's transplant team of heart and transplant specialists makes the final decision as to whether a donor heart is suitable for the patient.

Transplant procedure

When a heart becomes available and is approved for a patient, it is packed in a sterile cold solution and rushed to the hospital where the recipient is waiting. The heart can safely remain outside the body for only about four hours, so speed is critical. The recipient will be contacted to return immediately to the hospital if chronic care occurs outside of the hospital.

A general description of the transplant procedure follows. If the operation goes well, the actual surgery takes 4–10 hours.

- The patient undergoes final preoperative blood work and testing.
- General anesthesia is provided by an anesthesiologist experienced with cardiac patients.
- Intravenous antibiotics are given to prevent bacterial wound infections.
- The patient is put on a heart/lung machine, which performs the functions of the heart and lungs by pumping the blood to the rest of the body during surgery. This procedure is called cardiopulmonary bypass.
- Once the donor heart has arrived to the operating room, the patient's diseased heart is removed.
- The donor heart is attached to the patient's blood vessels, including the atria, pulmonary artery, and aorta.
- After the blood vessels are connected, the new heart is perfused with the patient's blood and begins beating. If the heart does not begin to beat immediately, the surgeon may use defibrillation (electric shock) to gain a productive rhythm.

WWW.BOOKBAZ.IR

KEY TERMS

Allograft—An organ or tissue from a genetically non-identical member of a species transplanted into a recipient of the same species. Human heart transplants are all allografts unless the donor is the identical twin of the recipient. When a transplant involves an organ taken from a different animal species, it is called a xenograft.

Angina—Also called angina pectoris, chest pain or discomfort that occurs when diseased blood vessels restrict blood flow to the heart.

Cardiopulmonary bypass—Mechanically circulating the blood with a heart-lung machine that bypasses the heart and lungs.

Complete blood count (CBC)—A blood test to check the numbers of red blood cells, white blood cells, and platelets in the blood.

Coronary artery disease—Also called atherosclerosis, it is a build-up of fatty matter and debris in the coronary artery wall that causes narrowing of the artery.

Crossmatch—A test to determine whether patient and donor tissues are compatible.

Echocardiogram—An imaging procedure used to create a picture of the heart's movement, valves, and chambers.

Electrocardiogram (ECG)—A test that measures electrical impulses in the heart.

Endomyocardial biopsy—Removal of a small sample of heart tissue to check for signs of damage caused by organ rejection.

End-stage heart failure—Severe heart disease that does not respond adequately to medical or surgical treatment.

Graft—To implant living tissue surgically. Graft also refers to the tissue that is transplanted.

Pulmonary hypertension—An increase in the pressure in the blood vessels of the lungs.

- The patient is taken off the heart-lung machine.
- The new heart is stimulated to maintain a regular beat with medications and/or a pacemaker for two to five days after surgery, until the new heart functions normally on its own.

There are two major types of heart transplantation procedures, orthotopic and heterotopic. In an orthotopic transplantation, the recipient's defective heart is completely removed and the donor heart inserted and sutured into place. In a heterotopic transplantation, the recipient's heart is left in place and the donor's heart is positioned so that the chambers and blood vessels of both organs can be connected to form a double heart. Heterotopic transplantations are most often performed for patients with severe **pulmonary hypertension**.

Heart transplant recipients are given immunosuppressive drugs to prevent the body from rejecting the new heart. These drugs are usually started before or during the heart transplant surgery. Immunosuppressive drugs keep the body's immune system from recognizing and attacking the new heart as foreign tissue. Normally, immune system cells recognize and attack foreign or abnormal cells such as bacteria, cancer cells, and cells from a transplanted organ. The drugs suppress the immune cells and allow the new heart to function properly; however, they can also allow infections and other adverse effects to occur to the patient because the patient's natural resistance to infections is suppressed.

The chance of rejection is highest during the first few months after the transplantation; therefore, recipients are usually given a combination of three or four immunosuppressive drugs in high doses during this time. Afterward, they must take maintenance doses of immunosuppressive drugs for the rest of their lives.

Cost and insurance coverage

The total cost for heart transplantation varies considerably, depending on where it is performed, whether transportation and lodging are needed, and whether there are any complications. The National Foundation for Transplants estimates that the cost for uncomplicated heart transplantation surgery and the first year of care in 2013 is about $787,000.

Insurance coverage for heart transplantation varies, depending on the policy. More than 80% of commercial insurers and 97% of Blue Cross/Blue Shield plans offered coverage for heart transplants as of 2013. Medicare pays for heart transplants if the surgery is performed at Medicare-approved centers. Medicaid pays for heart transplants in some states. Social workers at the transplant center can help patients and their families calculate their insurance coverage and put them in touch with nonprofit organizations that help transplant recipients when insurance is inadequate.

Preparation

Before patients are put on the transplant waiting list, their blood type is determined so a compatible

donor heart can be found. The heart must come from a person with the same blood type as the patient, unless it is blood type O negative. A blood type O negative heart is a universal donor and is suitable for any patient regardless of blood type.

A panel-reactive antibodies (PRA) test is also done before heart transplantation. This test tells doctors whether the patient is at high risk for having a hyperacute reaction against a donor heart. A hyperacute reaction is a strong immune response against the new heart that happens within minutes to hours after the new heart is transplanted. If the PRA shows that a patient is at high risk for this kind of reaction, then a crossmatch is done between a patient and a donor heart before transplant surgery. A crossmatch checks how close the match is between the patient's tissue type and the tissue type of the donor heart. Most people are not high risk, and a crossmatch usually is not done before the transplant because the surgery must be done as quickly as possible after a donor heart is found.

While waiting for heart transplantation, patients are given treatment to keep the heart as healthy as possible. They are regularly checked to make sure the heart is pumping enough blood. Intravenous medications may be used to improve cardiac output. If these drugs are not effective, a ventricular-assist device can maintain cardiac output until a donor heart becomes available.

Aftercare

Immediately following surgery, patients are monitored closely in the intensive care unit (ICU) of the hospital for 24–72 hours. Most patients need to receive oxygen for four to 24 hours following surgery. Continuous cardiac monitoring is used to diagnose and treat donor heart function. Renal, liver, brain, and pulmonary functions are carefully monitored during this time. Patients are then moved to a transplant unit where they remain a week or more.

Heart transplant patients start taking immunosuppressive drugs before or during surgery to prevent immune rejection of the heart. The drugs most commonly given to heart transplant patients are cyclosporine (Neoral, Sandimmune), mycophenolate mofetil (CellCept, Myfortic), tacrolimus (Prograf), and prednisone (or another steroid). High doses of immunosuppressive drugs are given at this time because rejection is most likely to happen within the first few months after the surgery. A few months after surgery, lower doses of immunosuppressive drugs usually are given, and then must be taken for the rest of the patient's life.

For about three months after the transplant surgery, patients usually come back to the transplant center twice a week for physical examinations and medical tests. These check for signs of infection, rejection of the new heart, or other complications.

In addition to **physical examination**, the following tests may be done during these visits:

- laboratory tests to check for infection
- chest x ray to check for early signs of lung infection
- electrocardiogram (ECG) to check heart function
- echocardiogram to check the function of the ventricles in the heart
- blood tests to check liver and kidney function
- complete blood counts (CBC) to check the numbers of blood cells
- taking a small tissue sample from the donor heart (endomyocardial biopsy) to check for signs of rejection

During the physical examination, blood pressure is checked and heart sounds are monitored with a stethoscope to determine if the heart is beating properly and pumping enough blood. Kidney and liver functions are checked because these organs may lose function if the heart is being rejected.

An endomyocardial biopsy is the removal of a small sample of the heart muscle. This procedure is done by **cardiac catheterization**. The heart muscle tissue is examined under a microscope for signs that the heart is being rejected. Endomyocardial biopsy is usually done weekly for the first four to eight weeks after transplant surgery, and then at longer intervals after that.

Risks

The most common and dangerous complications of heart transplant surgery are organ rejection and infection. Immunosuppressive drugs are given to prevent rejection of the heart. Most heart transplant patients have a rejection episode soon after transplantation. The signs of rejection include **shortness of breath**, **fever** and other flu-like symptoms, **fatigue**, new chest **pain**, weight gain due to fluid retention, and lowered urinary output. Rapid diagnosis ensures quick treatment, and when the response is quick, drug therapy is most successful. Rejection is treated with combinations of immunosuppressive drugs given in higher doses than immunosuppressive maintenance.

WWW.BOOKBAZ.IR

Most of these rejection situations are successfully treated.

Infection can result from the surgery, but most infections are a side effect of the immunosuppressive drugs. Immunosuppressive drugs keep the immune system from attacking the foreign cells of the donor heart; however, the suppressed immune cells are then unable to adequately fight bacteria, viruses, and other microorganisms. Microorganisms that normally do not affect persons with healthy immune systems can cause dangerous infections in transplant patients taking immunosuppressive drugs.

Patients are given **antibiotics** during surgery to prevent bacterial infection. They may also be given an antiviral drug to prevent virus infections. Patients who develop infections may need to have their immunosuppressive drugs changed or the dose adjusted. Infections are treated with antibiotics or other drugs, depending on the type of infection.

Other complications that can happen immediately after surgery are:

- bleeding
- pressure on the heart caused by fluid in the space surrounding the heart (pericardial tamponade)
- irregular heart rhythm
- reduced cardiac output
- increased amount of blood in the circulatory system
- decreased amount of blood in the circulatory system

Up to half of all heart transplant patients develop coronary artery disease one to five years after the transplant. The coronary arteries supply blood to the heart. Patients with this problem develop chest pains called **angina**. Other names for this complication are coronary allograft **vascular disease** (CAV) and chronic rejection. The only treatment for these complications is retransplantation.

Other long-term risks of heart transplantation and immunosuppressive drugs include **osteoporosis**, diabetes, high blood pressure, kidney disorders, and cancer—particularly **skin cancer** and lymphoma.

Results

Heart transplantation is an appropriate treatment for many patients with end-stage heart failure. The outcomes of heart transplantation depend on the patient's age, health, and other factors. According to data collected by the National Heart, Lung, and Blood Institute (NHLBI), 88% of transplant recipients survive one year. During the first year, infection and acute rejection are the leading causes of death. The three-year survival rate is 82%, the five-year survival rate is 75%, and the 10-year survival rate is 56%.

After transplant, most patients regain normal heart function, meaning that the heart pumps a normal amount of blood. A transplanted heart usually beats slightly faster than normal because the heart nerves are cut during surgery. The new heart also does not increase its rate as quickly during **exercise**. Even so, most patients feel much better and their capacity for exercise is dramatically improved from the period before they received the new heart. About 90% of survivors at five years will have no symptoms of heart failure. Some patients return to work (about 30%, according to the NHLBI) and other daily activities. Many are able to participate in sports.

Alternatives

End-stage heart disease is associated with a high mortality rate even with associated medical treatment. A ventricular-assist device (VAD) can be a viable alternative for patients not eligible for cardiac transplant or who are awaiting a donor heart; improvements in VADs since the early 2000s have led to the increased use of these devices, particularly in patients with **congenital heart disease**. Such therapies as the total artificial heart may provide other alternatives for the transplant candidate in the future. Other future possibilities include genetic therapy as well as tissue engineering to develop cardiac patches or tissue scaffolding that would allow a damaged heart to repair itself so that transplantation would be unnecessary.

Heart valve repair

Definition

Heart valve repair is a surgical procedure used to correct a malfunctioning heart valve. Repair usually involves separating the valve leaflets (the one-way "doors" of the heart valve that open and close to pump blood through the heart) or forcing them open with a balloon catheter, a technique known as balloon valvuloplasty.

Purpose

Heart valve repair is used to correct damage to the mitral, aortic, pulmonary, or tricuspid heart valves caused by a systemic infection, **endocarditis**, rheumatic **heart disease**, a congenital heart defect, or mitral and/or aortic valve disease. Damaged valves may not open properly (stenosis) or they may not close adequately (valve regurgitation, insufficiency, or incompetence).

Precautions

Patients who have a diseased heart valve that is badly scarred or calcified may be better candidates for valve replacement surgery.

Description

Heart valve repair is performed in a hospital setting by a cardiac surgeon. During valve repair surgery, the patient's heart is stopped, and his/her blood is circulated outside of the body through an extracorporeal bypass circuit, also called heart-lung machine or just "the pump." The extracorporeal circuit consists of tubing and medical devices that take over the function of the patient's heart and lungs during the procedure. As blood passes through the circuit, carbon dioxide is removed from the bloodstream and replaced with oxygen. The oxygenated blood is then returned to the body. Other components may also be added to the circuit to filter fluids from the blood or concentrate red blood cells.

WWW.BOOKBAZ.IR

In cases of valve disease where the leaflets have become fused together, a procedure known as a valvulotomy is performed. In valvulotomy, the leaflets of the valves are surgically separated, or partially resected, with an incision to increase the size of the valve opening. The surgeon may also make adjustments to the chordae, the cord-like tissue that connects the valve leaflets to the ventricle muscles, to improve valve function.

Another valve repair technique, **balloon valvuloplasty**, is used in patients with pulmonary, aortic, and **mitral valve stenosis** to force open the valve. Valvuloplasty is similar to a cardiac **angioplasty** procedure in that it involves the placement of a balloon-tipped catheter into the heart. Once inserted into the valve, the balloon is inflated and the valve dilates, or opens. Valvuloplasty does not require a bypass circuit.

Preparation

A number of diagnostic tests may be administered prior to valve repair surgery. **Magnetic resonance imaging** (MRI), echocardiogram, angiogram, and/or scintigram are used to help the surgeon get an accurate picture of the extent of damage to the heart valve and the status of the coronary arteries.

Aftercare

The patient's blood pressure and vital signs will be carefully monitored following a valve repair procedure, and he or she watched closely for signs of **edema** or **congestive heart failure**.

Echocardiography or other diagnostic tests are ordered for the patient at some point during or after surgery to evaluate valvular function. A **cardiac rehabilitation** program may also be recommended to assist the patient in improving **exercise** tolerance after the procedure.

Risks

As with any invasive surgical procedure, hemorrhage, infarction, **stroke**, **heart attack**, and infection are all possible complications of heart valve repair. The overall risks involved with the surgery depend largely on the complexity of the procedure and physical condition of the patient.

Results

Ideally, a successful heart valve repair procedure will return heart function to age-appropriate levels. If valvuloplasty is performed, a follow-up valve repair or replacement surgery may be necessary at a later date.

KEY TERMS

Angiogram—An angiogram uses a radiopaque substance, or dye, to make the blood vessels or arteries visible under x ray.

Calcified—Hardened by calcium deposits.

Catheter—A long, thin, flexible tube used in valvuloplasty to widen the valve opening.

Echocardiogram—Ultrasound of the heart; generates a picture of the heart through the use of soundwaves.

Edema—Fluid accumulation in the body.

Scintigram—A nuclear angiogram; a scintigram involves injection of a radioactive substance into the patient's circulatory system. As the substance travels through the body, a special scanning camera takes pictures.

Stenosis—Narrowing of the heart valve opening.

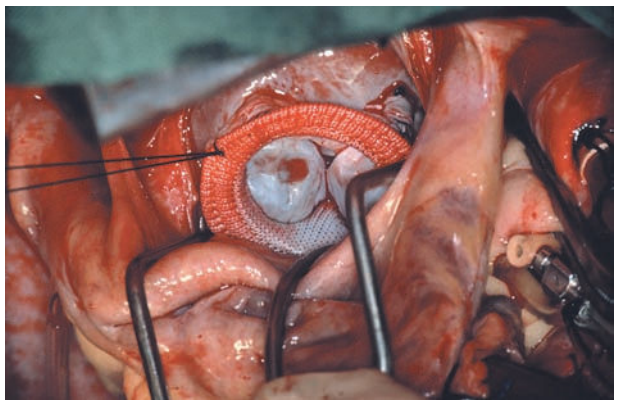
Heart valve replacement

Definition

Heart valve replacement is a surgical procedure during which surgeons remove a damaged valve from the heart and substitute a healthy one.

Purpose

Four valves direct blood to and from the body through the heart: the aortic valve, the pulmonic valve, the tricuspid valve, and the mitral valve. Any of these valves may malfunction because of a birth defect, infection, disease, or **trauma**. When the malfunction is so severe that it interferes with blood flow, an individual will have heart **palpitations**, **fainting** spells, and/or difficulty breathing. These symptoms will progressively worsen and cause death unless the damaged valve is replaced surgically.



Open heart surgery showing replacement of a valve. *(David Leah/Photo Researchers, Inc.)*

Precautions

Abnormal tricuspid valves usually are not replaced because they do not cause serious symptoms. Mildly or even moderately diseased mitral valves may not need to be replaced because their symptoms are tolerable or they can be treated with such drugs as **beta blockers** or **calcium** antagonists, which slow the heart rate. However, a severely diseased mitral valve should be repaired or replaced unless the person is too ill to tolerate the operation because of another condition or illness.

Description

After cutting through and separating the breastbone and ribs, surgeons place the patient on a cardiopulmonary bypass machine, which will perform the functions of the heart and lungs during the operation. They then open the heart and locate the faulty valve. Slicing around the edges of the valve, they loosen it from the tendons that connect it to the rest of the heart and withdraw it. The new valve is inserted and sutured into place. The patient is then taken off the bypass machine and the chest is closed. The surgery takes three to five hours and is covered by most insurance plans.

There are three types of replacement valves. One class is made from animal tissue, usually a pig's aortic valve. Another is mechanical and is made of metal and plastic. The third includes human valves that have been removed from an organ donor or that, rarely, are the patient's own pulmonic valve.

There is no single ideal replacement valve. The choice between an animal valve or a mechanical valve depends largely on the age of the patient. Because valves obtained from animals have a life expectancy of 7–15 years, they usually are given to older patients. Mechanical valves are used in younger patients because they are more durable. Because mechanical valves are made of foreign material **blood clots** can form on their surface. Therefore, patients who receive these valves must take anticoagulants the rest of their lives.

Donor or pulmonic valves are given only to those patients who will deteriorate rapidly because of a narrowing of the passageway between the aorta and the left ventrical (aortic stenosis). These valves are limited in their use because of the small supply available from donors and the strain that could be caused by removing and transferring a patient's own pulmonic valve.

Preparation

Before patients undergo heart valve replacement, they must be evaluated carefully for any signs that they may not tolerate the surgery.

Preoperative tests include:

- electrocardiography, which assesses the electrical activity of the heart
- echocardiography, which uses sound waves to show the extent of the obstruction of blood flow through the heart and determine the degree of loss of heart function due to the malfunctioning valve
- chest x ray, which provides an overall view of the anatomy of the heart and the lungs

Cardiac catheterization may also be performed to further asses the valve and to determine if coronary bypass surgery should also be done.

Aftercare

A patient usually spends one to three days in the hospital intensive care unit (ICU) after heart valve replacement so that the working of his or her heart and circulation can be monitored closely. When first brought to the ICU after surgery, the patient undergoes a neurological examination to be sure he or she has not suffered a **stroke**. The patient continues to breathe by means of a tube inserted in the trachea at the time of surgery. This mechanical ventilation is not withdrawn until the patient is fully awake from **anesthesia**, shows signs that he or she can breathe satisfactorily without mechanical support, and has steadfast circulation.

Once stablilized, the patient is transferred to a standard medical/surgical unit where he or she receives drugs that will prevent excess fluid from building up around the heart. As soon as possible, the patient begins walking and exercising to regain strength. He or she is also placed on a diet that is low in salt and **cholesterol**.

WWW.BOOKBAZ.IR

KEY TERMS

Anticoagulants—Drugs that prevent blood clots from forming.

Aortic valve—A fold in the channel leading from the aorta to the left ventricle of the heart. The aortic valve directs blood flow that has received oxygen from the lungs to the aorta, which transmits blood to the rest of the body.

Cardiac catheterization—A thin tube called a catheter is inserted into an artery or vein in the leg, groin or arm. The catheter tube is carefully threaded into the area of the heart needing surgical repair. A local anaesthesia is used at the insertion sites.

Cardiopulmonary bypass machine—A mechanical instrument that takes over the circulation of the body while heart surgery is taking place.

Echocardiography—A diagnostic instrument that assesses the structure of the heart using sound waves.

Electrocardiography—A diagnostic instrument that evaluates the function of the heart by measuring the electrical activity generated by the beating of the heart.

Mitral valve—A fold in between the left atrium and the left ventricle of the heart that directs blood that has received oxygen from the lungs to the aortic valve and the aorta.

Pulmonic valve—A fold in the pulmonary artery that directs blood to the lungs. It may be transferred to replace a severely diseased aortic valve during heart valve replacement surgery for aortic stenosis.

Tricuspid valve—A fold in between the right atrium and the right ventricle of the heart that directs blood that needs oxygen to the lungs.

After being released from the hospital, the patient continues a daily **exercise** program that includes vigorous walking, and he or she may also join a recommended **cardiac rehabilitation** program. He or she usually can return to work or other normal activities within two months of the surgery.

Risks

Complications following heart valve replacement are not common, but can be serious. All valves made from animal tissue will develop calcium deposits over time. If these deposits hamper the function of the valve, it must be replaced. Valves may become dislodged. Blood clots may form on the surface of the substitute valve, break off into the general circulation, and become wedged in an artery supplying blood to the brain, kidneys, or legs. These blood clots may cause fainting spells, stroke, kidney failure, or loss of circulation to the legs. These blood clots can be treated with drugs or surgery.

Infection of heart muscle affects up to 2% of patients who have heart valve replacement. Such an infection is treated with intravenous **antibiotics**. If the infection persists, the new valve may have to be replaced.

Results

Few patients die as a result of the surgery. Approximately 3% of all patients die during or immediately after heart valve replacement, and less than 1% of patients below the age of 65 die because of the operation. The vast majority of patients who have heart valve replacement return to normal activity after the surgery. Depending on the type of valve they receive, these patients will have no symptoms of valve abnormality for at least seven years. Also, their quality of life will improve because they may no longer have difficulty breathing, fainting spells, or palpitations.

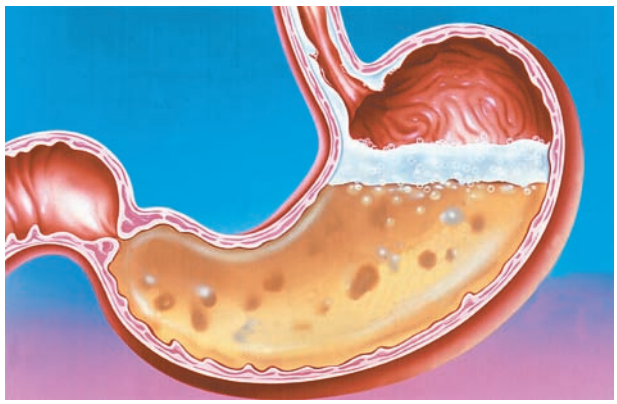
Heartburn

Definition

Heartburn is a burning sensation in the chest that can extend to the neck, throat, and face; it is worsened by bending or lying down. It is the primary symptom of gastroesophageal reflux, which is the movement of



An illustration of foaming antacid on top of the contents of a human stomach. Heartburn is caused by a backflow of the stomach's acidic contents into the esophagus, causing inflammation and a sense of pain that can rise to the throat. *(Custom Medical Stock Photo, Inc.)*

stomach acid into the esophagus. On rare occasions, it is due to **gastritis** (stomach lining inflammation).

Description

More than one-third of the population is afflicted by heartburn, with about one-tenth afflicted daily. Infrequent heartburn is usually without serious consequences, but chronic or frequent heartburn (recurring more than twice per week) can have severe consequences. Accordingly, early management is important.

Understanding heartburn depends on understanding the structure and action of the esophagus. The esophagus is a tube connecting the throat to the stomach. It is about 10 in. (25 cm) long in adults, lined with squamous (plate-like) epithelial cells, coated with mucus, and surrounded by muscles that push food to the stomach by sequential waves of contraction (peristalsis). The lower esophageal sphincter (LES) is a thick band of muscles that encircles the esophagus just above the uppermost part of the stomach. This sphincter is usually tightly closed and normally opens only when food passes from the esophagus into the stomach. Thus, the contents of the stomach are normally kept from moving back into the esophagus.

The stomach has a thick mucous coating that protects it from the strong acid it secretes into its interior when food is present, but the much thinner esophageal coating does not provide protection against acid. Thus, if the LES opens inappropriately or fails to close completely, and stomach contents leak into the esophagus, the esophagus can be burned by acid. The resulting burning sensation is called heartburn.

Occasional heartburn has no serious long-lasting effects, but repeated episodes of gastroesophageal reflux can ultimately lead to esophageal inflammation (esophagitis) and other damage. If episodes occur more frequently than twice a week, and the esophagus is repeatedly subjected to acid and digestive enzymes from the stomach, ulcerations, scarring, and thickening of the esophagus walls can result. This thickening of the esophagus wall causes a narrowing of the interior of the esophagus. Such narrowing affects swallowing and peristaltic movements. Repeated irritation can also result in changes in the types of cells that line the esophagus. The condition associated with these changes is termed Barrett's syndrome and can lead to **esophageal cancer**.

Causes and symptoms

Causes

A number of different factors may contribute to LES malfunction with its consequent gastroesophageal acid reflux:

- The eating of large meals that distend the stomach can cause the LES to open inappropriately.
- Lying down within two to three hours of eating can cause the LES to open.
- Obesity, pregnancy, and tight clothing can impair the ability of the LES to stay closed by putting pressure on the abdomen.
- Certain drugs, notably nicotine, alcohol, diazepam (Valium), meperidine (Demerol), theophylline, morphine, prostaglandins, calcium channel blockers, nitrate heart medications, anticholinergic and adrenergic drugs (drugs that limit nerve reactions), including dopamine, can relax the LES.
- Progesterone is thought to relax the LES.
- Greasy foods and some other foods such as chocolate, coffee, and peppermint can relax the LES.
- Paralysis and scleroderma can cause the LES to malfunction.
- Hiatal hernia may also cause heartburn according to some gastroenterologists. (Hiatal hernia is a protrusion of part of the stomach through the diaphragm to a position next to the esophagus.)

Symptoms

Heartburn itself is a symptom. Other symptoms also caused by gastroesophageal reflux can be associated with heartburn. Often people with heartburn salivate excessively or regurgitate stomach contents into their mouths, leaving a sour or bitter taste. Frequent gastroesophageal reflux leads to additional

WWW.BOOKBAZ.IR

complications including difficult or painful swallowing, **sore throat**, hoarseness, coughing, **laryngitis**, **wheezing**, **asthma**, **pneumonia**, gingivitis, **bad breath**, and earache.

Diagnosis

Gastroenterologists and internists are best equipped to diagnose and treat gastroesophageal reflux. Diagnosis is usually based solely on patient histories that report heartburn and other related symptoms. Additional diagnostic procedures can confirm the diagnosis and assess damage to the esophagus, as well as monitor healing progress. The following diagnostic procedures are appropriate for anyone who has frequent, chronic, or difficult-to-treat heartburn or any of the complicating symptoms.

X rays taken after a patient swallows a barium suspension can reveal esophageal narrowing, ulcerations, or a reflux episode as it occurs. However, this procedure cannot detect the structural changes associated with different degrees of esophagitis. This diagnostic procedure has traditionally been called the "upper GI series" or "barium swallow" and costs about $250.00.

Esophagoscopy is a newer procedure that uses a thin flexible tube to view the inside of the esophagus directly. It should be done by a gastroenterologist or gastrointestinal endoscopist and costs about $700. It gives an accurate picture of any damage present and gives the physician the ability to distinguish between different degrees of esophagitis.

Other tests may also be used. They include pressure measurements of the LES; measurements of esophageal acidity (pH), usually throughout a 24-hour period; and microscopic examination of biopsied tissue from the esophageal wall (to inspect esophageal cell structure for Barrett's syndrome and malignancies).

Newer technology allows for continuous monitoring of pH levels to help determine the cause. A tiny wireless capsule can be delivered to the lining of the esophagus through a catheter and data recorder on a device the size of a pager that is clipped to the patient's belt or purse for 48 hours. The capsule eventually sloughs off and passes harmlessly through the gastrointestinal tract in 7–10 days.

A burning sensation in the chest is usually heartburn and is not associated with the heart. However, chest **pain** that radiates into the arms and is not accompanied by regurgitation is a warning of a possible serious heart problem. Anyone with these symptoms should contact a doctor immediately.

Treatment

Drugs

Occasional heartburn is probably best treated with over-the-counter **antacids**. These products go straight to the esophagus and immediately begin to decrease acidity. However, they should not be used as the sole treatment for patients who either have two or more episodes per week or who have heartburn periods of more than three weeks. There is a risk of kidney damage and other metabolic changes.

H2 blockers (histamine receptor blockers, such as Pepcid AC, Zantac, Tagamet) decrease stomach acid production and are effective against heartburn. H2 blocker treatment also allows healing of esophageal damage but is not very effective when there is a high degree of damage. It takes 30–45 minutes for these drugs to take effect, so they must be taken prior to an episode. Thus, they should be taken daily, usually two to four times per day for several weeks. Six to 12 weeks of standard-dose treatment relieves symptoms in about one-half the patients. Higher doses relieve symptoms in a greater fraction of the population, but at least 25% of patients are not helped by H2 blockers.

Proton-pump inhibitors also inhibit acid production by the stomach, but are much more effective than H2 blockers for some people. They are also more effective in aiding the healing process. Esophagitis is healed in about 90% of the patients undergoing proton-pump inhibitor treatment.

The long-term effects of inhibiting stomach acid production are unknown. Without the antiseptic effects of a consistently acidic stomach environment, users of H2 blockers or proton-pump inhibitors may become more susceptible to bacterial and viral infection. Absorption of some drugs is also lowered by this less-acidic environment.

Prokinetic agents (also known as motility drugs) act on the LES, stimulating it to close more tightly, thereby keeping stomach contents out of the esophagus. It is not known how effectively these drugs promote healing. Some of the early motility drugs had serious neurological side effects, but a newer drug, cisapride, seems to act only on digestive system nerve connections.

Surgery

Fundoplication, a surgical procedure to increase pressure on the LES by stretching and wrapping the upper part of the stomach around the sphincter, is a treatment of last resort. About 10% of people with

heartburn undergo this procedure. It is not always effective and its effectiveness may decrease over time, especially several years after surgery. Dr. Robert Marks and his colleagues at the University of Alabama reported in 1997 on the long-term outcome of this procedure. They found that 64% of the patients in their study who had fundoplication between 1992 and 1995 still had heartburn and reported an impaired quality of life after the surgery.

Laparoscopy (an examination of the interior of the abdomen by means of the laparoscope) now provides hope for better outcomes. Fundoplication performed with a laparoscope is less invasive. Five small incisions are required instead of one large incision. Patients recover faster, and it is likely that studies will show they have fewer surgical complications.

Nutrition and dietary concerns

Prevention is a primary feature for heartburn management in alternative medicine and traditional medicine. Dietary adjustments can eliminate many causes of heartburn.

Herbal remedies include bananas, aloe vera gel, chamomile (*Matricaria recutita*), ginger (*Zingiber officinale*), and citrus juices, but there is little agreement here. For example, ginger, which seems to help some people, is claimed by other practitioners to cause heartburn and is thought to relax the LES. There are also many recommendations to avoid citrus juices, which are themselves acidic. Licorice (*Glycyrrhiza uralensis*) can help relieve the symptoms of heartburn by reestablishing balance in the acid output of the stomach.

Several homeopathic remedies are useful in treating heartburn symptoms. Among those most often recommended are *Nux vomica, Carbo vegetabilis*, and *Arsenicum album*. **Acupressure** and **acupuncture** may also be helpful in treating heartburn.

Sodium bicarbonate (baking soda) is an inexpensive alternative to use as an antacid. It reduces esophageal acidity immediately, but its effect is not long-lasting and should not be used by people on sodium-restricted **diets**.

Prognosis

The prognosis for people who get heartburn only occasionally or people without esophageal damage is excellent. The prognosis for people with esophageal damage who become involved in a treatment program that promotes healing is also excellent. The prognosis for anyone with esophageal cancer is very poor. There is a strong likelihood of a painful illness and a less than 5% chance of surviving more than five years.

KEY TERMS

Barrett's syndrome—Also called Barrett's esophagus or Barrett's epithelia; a condition where the squamous epithelial cells that normally line the esophagus are replaced by thicker columnar epithelial cells.

Digestive enzymes—Molecules that catalyze the breakdown of large molecules (usually food) into smaller molecules.

Esophagitis—Inflammation of the esophagus.

Fundoplication—A surgical procedure that increases pressure on the LES by stretching and wrapping the upper part of the stomach around the sphincter.

Gastroesophageal reflux—The flow of stomach contents into the esophagus.

Hiatal hernia—A protrusion of part of the stomach through the diaphragm to a position next to the esophagus.

Metabolic—Refers to the chemical reactions in living things.

Mucus—Thick, viscous, gel-like material that functions to moisten and protect inner body surfaces.

Peristalsis—A sequence of muscle contractions that progressively squeeze one small section of the digestive tract and then the next to push food along the tract, similar to pushing toothpaste out of its tube.

Scleroderma—An autoimmune disease with many consequences, including esophageal wall thickening.

Squamous epithelial cells—Thin, flat cells found in layers or sheets covering surfaces such as skin and the linings of blood vessels and esophagus.

Ulceration—An open break in surface tissue.

Prevention

Given the lack of completely satisfactory treatments for heartburn or its consequences and the lack of a cure for esophageal cancer, prevention is of the utmost importance. Proponents of traditional and alternative medicine agree that people disposed to heartburn should:

- Avoid eating large meals.
- Avoid alcohol, caffeine, fatty foods, fried foods, hot or spicy foods, chocolate, peppermint, and nicotine.

WWW.BOOKBAZ.IR

- Avoid drugs known to contribute to heartburn, such as nitrates (heart medications such as Isonate and Nitrocap), calcium channel blockers (e.g., Cardizem and Procardia), and anticholinergic drugs (e.g., Probanthine and Bentyl), and check with their doctors about any drugs they are taking.
- Avoid clothing that fits tightly around the abdomen.
- Control body weight.
- Wait about three hours after eating before going to bed or lying down.
- Elevate the head of the bed 6–9 in. (15–23 cm) to alleviate heartburn at night. This can be done with bricks under the bed or with a wedge designed for this purpose.

Preventing heartburn's switch to cancer begins with preventing heartburn in the first place. A study in Great Britain in 2004 looked at using a combination of **aspirin** and an anti-ulcer drug to try to prevent Barrett's esophagus from forming in patients with long-term heartburn. Aspirin has been found in previous studies to reduce cases of esophageal cancer. However, since one of its side effects is an increased risk of stomach **ulcers**, the researchers were including an effective anti-ulcer drug for participants.

REVISED BY TERESA G. ODLE

Heartland virus

Definition

Heartland virus (HRTV) is a phlebovirus, a member of a genus of viruses belonging to the Bunyaviridae family. These are RNA viruses carried by insect vectors, usually sandflies or ticks. Heartland virus is the first phlebovirus to be discovered in North America. It is named for Heartland Regional Medical Center in St. Joseph, Missouri, where it was first identified in 2009 by Dr. Scott Folk, an infectious diseases expert.

Description

Heartland virus is closely related to Bhanja virus, a phlebovirus first documented in India in 1974, and to SFTS virus, a phlebovirus that emerged in northeastern and central China in 2009. SFTS virus has a fatality rate of 12%. All three phleboviruses are tick-borne and identified as causes of emerging infectious diseases or EIDs. All three EIDs are also classified as zoonoses. Heartland virus is carried to humans by the Lone Star tick, *Amblyomma americanum*, which transmits the virus while feeding on blood. The Lone Star tick is widely distributed in the continental United States; it is found in the Midwest from Texas as far north as

Iowa; in all the southeastern states; and along the East Coast as far north as Maine.

The Heartland virus was first identified in humans in the summer of 2009, when two Missouri farmers came to the regional medical center with **fever** and other symptoms that led doctors to suspect **ehrlichiosis**, a bacterial infection carried by ticks. When the patients did not respond to doxycycline, an antibiotic that is standard treatment for ehrlichiosis, samples of their blood were sent to the Centers for Disease Control and Prevention (CDC) for analysis. The causative organism was found to be a phlebovirus.

As of May 2014, only 10 cases of Heartland virus have been confirmed by the CDC, in patients in Missouri, Oklahoma, and Tennessee. Two of the patients died. Given the wide distribution of the Lone Star tick and the fact that ticks are most active in the summer, more cases were expected before the end of 2014.

Risk factors

Known risk factors for Heartland virus infection include:

- living in the parts of the United States where the Lone Star tick is known to live
- working or hiking outside during the warmer months (April through September), when ticks are most active
- working or hiking in underbrush or bushy or wooded areas
- working or living on a farm

Demographics

It is difficult to determine the demographics of Heartland virus from the 10 cases confirmed as of mid-2014, except that all occurred in middle-aged or older males.

Causes and symptoms

The cause of Heartland virus infection is a phlebovirus transmitted to humans through the bite of a tick, *Amblyomma americanum*. It is not known whether other tick species may be vectors of the phlebovirus.

The symptoms of Heartland virus infection include:

- high fever, as high as 104°F (40°C)
- muscle aches
- leukopenia (low levels of white cells in the blood)
- thrombocytopenia (low levels of platelets in the blood)
- fatigue
- nausea
- loss of appetite
- bruising easily
- diarrhea

Diagnosis

There was no diagnostic test specific for Heartland virus as of late summer 2014, although researchers at the CDC were working on developing such a test. People who have the symptoms of Heartland virus should consult their doctor as soon as possible.

Treatment

There was no specific treatment for Heartland virus infection as of 2014, as viruses cannot be treated with doxycycline or any other antibiotic. Treatment is primarily supportive. The patient may require hospitalization for intravenous fluids and treatment of **pain** and fever.

Prognosis

The prognosis depends on the patient's general health; the two patients who died as of mid-2014 from the phlebovirus were both older adults with concurrent health problems.

Prevention

There were no vaccines to prevent Heartland virus as of 2014. Preventive measures consisted chiefly of avoiding exposure to ticks and checking for ticks after coming indoors.

Specific preventive measures recommended by the CDC include the following:

- When hiking, walk in the center of the trail rather than in high grass or wooded areas.
- To repel ticks, use repellents that contain 20–30% DEET (N, N-diethyl-m-toluamide) on exposed skin and clothing. Permethrin in 0.5% concentration can be used to repel ticks from clothing and boots, pants, socks and tents. Permethrin will last through several washings.
- Bathe or shower as soon as possible (within 2 hours) after coming indoors to find any ticks that may be on the body. Conduct a full-body search, using a hand-held or full-length mirror to view all parts of the body.
- Check children, pets, clothing, and such items as backpacks when entering the house after being in a tick-infested area.

WWW.BOOKBAZ.IR

KEY TERMS

Emerging infectious disease (EID)—An infectious disease whose incidence has increased within the last 35 years and may increase further in the near future.

Leukopenia—A decrease in the number of white blood cells in the blood.

Phlebovirus—A genus of RNA viruses that belongs to the family Bunyaviridae. Heartland virus is a phlebovirus.

Zoonosis (pl. zoonoses)—Any disease that can be transmitted from other animals to humans, or from humans to other animals.

- Place clothing in a dryer at high heat for an hour to kill any remaining ticks.
- Regarding pets, dogs should be checked for ticks each time after going outside and checked by the veterinarian at each visit. Tick repellents are also available for use on dogs. Keep cats indoors whenever possible, preferably permanently. Never apply a flea or tick repellent intended for dogs to a cat: cats are extremely sensitive to many chemicals and may be fatally poisoned by insect repellents for dogs. Insect repellents for household pets are species-specific.

Heat cramps *see* **Heat disorders**

Heat disorders

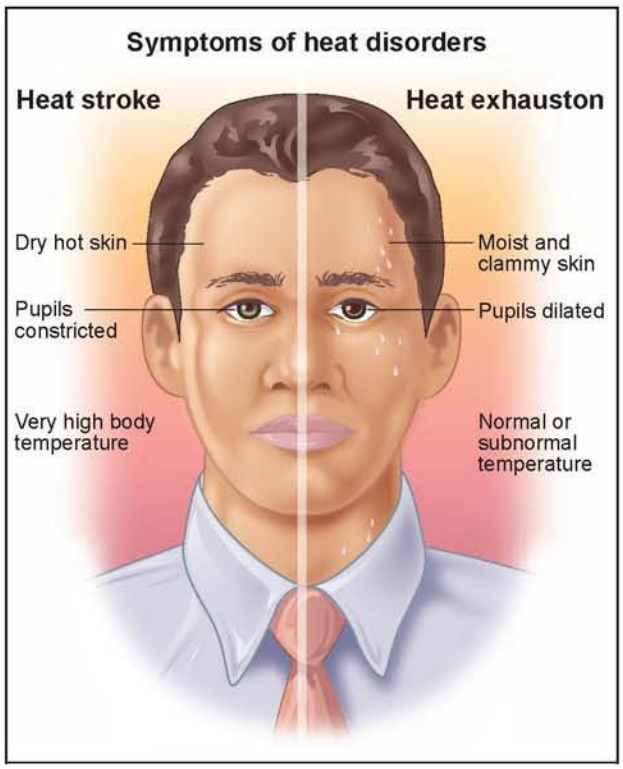
Definition

Heat disorders are a group of physically related illnesses caused by prolonged exposure to hot temperatures, restricted fluid intake, or failure of the body's temperature regulation mechanisms. Disorders of heat exposure include heat cramps, heat exhaustion, and heat stroke (also called sunstroke). Hyperthermia is the general name given to heat-related illnesses. The two most common forms of hyperthermia are heat exhaustion and heat stroke, which is especially dangerous and requires immediate medical attention.

Description

Heat disorders are harmful to people of all ages, but their severity is likely to increase as people age. Heat cramps in a 16-year-old may be heat exhaustion in a 45-year-old and heat stroke in a 65-year-old.

Regardless of extreme weather conditions, the healthy human body keeps a steady temperature of approximately 98.6°F (37°C). The body's temperature regulating mechanisms rely on the thermal regulating centers in the brain. Through these complex centers, the body tries to adapt to high temperatures by adjusting



Symptoms of heat stroke and heat exhaustion. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

the amount of salt in the perspiration. Salt helps the cells in body tissues retain water. In hot weather, a healthy body will lose enough water to cool the body while creating the lowest level of chemical imbalance. In hot weather, or during vigorous activity, the body perspires. As perspiration evaporates from the skin, the body is cooled. If the body loses too much salt and fluids, the symptoms of **dehydration** can occur.

Demographics

Anyone can develop hyperthermia. However, seniors and young children are more likely to be affected than are young or middle-aged adults. In addition, workers at risk of heat **stress** include anyone who works outdoors or indoors in hot conditions such as bakery workers, boiler room workers, factory workers, farmers, and firefighters. Workers are at greater risk of heat disorders if they are overweight, 65 years of age or older, have **heart disease** or high blood pressure, or take medications that may be affected by hot temperatures. The U.S. Centers for Disease Control and Prevention (CDC) report that more than 330 Americans die of heat-related causes each year. More deaths occur in years that have significant heat waves, and more individuals die of heat-related illness during the summer months. More than 40% of the individuals who die of heat-related causes each year are over the age of 65.

Causes and symptoms

The causes and symptoms of heat disorders, whether they be heat cramps, heat exhaustion, or heatstroke, are similar in many respects but differ in their severity and in other important considerations.

Heat cramps

Heat cramps are painful **muscle spasms** caused by the excessive loss of salts (electrolytes) due to heavy perspiration. The muscle tissue becomes less flexible, causing **pain**, difficult movement, and involuntary tightness. Heavy exertion in extreme heat, restricted fluid intake, or failure of temperature regulation mechanisms of the body may lead to heat cramps. This disorder occurs more often in the legs and abdomen than in other areas of the body. Individuals at higher risk are those working in extreme heat, elderly people, young children, people with health problems, and those who are unable to naturally and properly cool their bodies. Individuals with poor circulation and who take medications to reduce excess body fluids (**diuretics**) can be at risk when conditions are hot and humid.

Heat exhaustion

Heat exhaustion is caused by exposure to high heat and humidity for many hours, resulting in excessive loss of fluids and salts through heavy perspiration. The skin may appear cool, moist, and pale. The individual may complain of **headache** and nausea with a feeling of overall weakness and exhaustion. **Dizziness**, faintness, and mental confusion are often present, as is rapid and weak pulse. Breathing becomes fast and shallow. Fluid loss reduces blood volume and lowers blood pressure. Yellow or orange urine often is a result of inadequate fluid intake, along with associated intense thirst. Insufficient water and salt intake or a deficiency in the production of sweat place an individual at high risk for heat exhaustion.

Heatstroke

Heatstroke is caused by overexposure to extreme heat, resulting in a breakdown in the body's heat regulating mechanisms. The body's temperature reaches a dangerous level, as high as 106°F (41.1°C). An individual with heatstroke has a body temperature

WWW.BOOKBAZ.IR

higher than 104°F (40°C). Other symptoms are mental confusion with possible combativeness and bizarre behavior, staggering, and faintness.

The pulse becomes strong and rapid (160–180 beats per minute) with the skin taking on a dry and flushed appearance. There is often very little perspiration. The individual can quickly lose consciousness or have convulsions. Before heat stroke, an individual experiences heat exhaustion and the associated symptoms. When the body can no longer maintain a normal temperature, heat exhaustion becomes heatstroke. Heatstroke is a life-threatening medical emergency that requires immediate initiation of life-saving measures.

Diagnosis

The diagnosis of heat cramps usually involves observation of symptoms such as muscle cramping and thirst. Diagnosis of heat exhaustion or heatstroke, however, may require a physician to review the medical history, document symptoms, and obtain a blood pressure and temperature reading. The physician also may take blood and urine samples for further laboratory testing. A test to measure the body's electrolytes also can give valuable information about chemical imbalances caused by the heat-related illness.

Treatment

Treatment varies depending on whether the heat disorder is a case of heat cramps, heat exhaustion, or heatstroke.

Heat cramps

The care of heat cramps includes placing the individual at rest in a cool environment, while giving cool water with one teaspoon of salt per quart of water or giving a commercial sports drink (e.g., Gatorade). Usually, rest and liquids are all that is needed for the patient to recover. Mild stretching and massaging of the muscle area follows once the condition improves. The individual should not take salt tablets since this may actually worsen the condition. When the cramps stop, the person usually can start activity again if there are no other signs of illness. The individual needs to continue drinking fluids and should be watched carefully for further signs of heat-related illnesses.

Heat exhaustion

An individual who shows signs of heat exhaustion should stop all physical activity and immediately be moved to a cool place out of the Sun, preferably a cool, air-conditioned location. She or he should then lay down with feet slightly elevated, remove or loosen clothing, and drink cold (but not iced), slightly salty water or a commercial sports drink. Rest and replacement of fluids and salt is usually all the treatment that is needed, and hospitalization is rarely required. Following rehydration, the person usually recovers rapidly.

Heatstroke

Simply moving the individual afflicted with heatstroke to a cooler place is not enough to reverse internal overheating. Emergency medical assistance should be called immediately. While waiting for help to arrive, quick action to lower body temperature must take place. Treatment involves getting the victim to a cool place, loosening clothes or undressing the heat stroke victim, and allowing air to circulate around the body. The next important step is wrapping the individual in wet towels or clothing, and placing ice packs in areas with the greatest blood supply. These areas include the neck, under the arm and knees, and in the groin. The individual can even be placed into a bathtub full of cool water to help speed cooling. A fan can be used to circulate air over dampened skin to simulate sweating and help the cooling process. Once the patient is under medical care, **cooling treatments** may continue as appropriate. The individual's body temperature will be monitored constantly to guard against overcooling. Breathing and heart rate will be monitored closely, and fluids and electrolytes will be replaced intravenously. **Anticonvulsant drugs** may be given to help reduce shivering, which warms the body up. After severe heat stroke, bed rest may be recommended for several days.

Risks

The very young, very old, individuals who are obese, and those with cardiovascular problems are at increased risk of experiencing a heat disorder. Alcohol and diseases that impair the ability to sweat are associated with a higher risk of heat-related illness.

Individuals taking certain medications are more likely to be affected because the medications can interfere with the body's normal cooling mechanisms. Individuals taking some blood pressure and heart medications, allergy medications, diet pills, water pills, cold medicines, medicines to prevent seizures, **laxatives**, and thyroid pills are at increased risk for hyperthermia.

Heat cramps

Heat cramps are the least severe of the heat-related illnesses. This heat disorder is often the first

signal that the body is having difficulty with increased temperature. Individuals exposed to excessive heat should think of heat cramps as a warning sign to a potential heat-related emergency.

Heat exhaustion

Heat exhaustion is a more serious and complex condition than heat cramps. Heat exhaustion can result from prolonged exposure to hot temperatures, restricted fluid intake, or failure of temperature regulation mechanisms of the body. It often affects athletes, firefighters, construction workers, factory workers, and anyone who wears heavy clothing in hot, humid weather.

Heatstroke

Heat exhaustion can develop rapidly into heatstroke. Heatstroke can be life threatening. Because of its seriousness and its high potential for causing death, immediate medical attention is critical when problems first begin. Heat stroke, like heat exhaustion, is also a result of prolonged exposure to hot temperatures, restricted fluid intake, or failure of temperature regulation mechanisms of the body. However, the severity of impact on the body is much greater with heatstroke.

Prognosis

Prompt treatment for heat cramps is usually very effective with the individual returning to activity thereafter. Treatment of heat exhaustion usually brings full recovery in one to two days. Heatstroke is a very serious condition and its outcome depends upon general health and age. Due to the high internal temperature of heatstroke, permanent damage to internal organs is possible.

Prevention

The best way to defend against heat-related illness is prevention. Because heat cramps, heat exhaustion, and heatstroke are all essentially different levels of severity of the same disorder, the prevention of the onset of all heat disorders is similar. Strenuous **exercise** should be avoided when it is very hot or humid. Individuals exposed to extreme heat conditions should drink plenty of fluids. Wearing light and loose-fitting clothing in hot weather is important, regardless of the activity. It is important to consume water often and not to wait until thirst develops. If perspiration is excessive, fluid intake should be increased. When urine output decreases, fluid intake should also increase. Eating lightly salted foods can help replace salts lost through perspiration. Ventilation in any working areas in warm weather must be adequate. This can be achieved as simply as opening a window or using an electric fan. Proper ventilation will promote adequate sweat evaporation to cool the skin.

KEY TERMS

Convulsions—Also termed seizures; a sudden violent contraction of a group of muscles.

Electrolyte—Ions in the body that participate in metabolic reactions. The major human electrolytes are sodium (Na^+), potassium (K^+), calcium ($Ca\ 2^+$), magnesium ($Mg2^+$), chloride (Cl^-), phosphate (HPO_4^{2-}), bicarbonate (HCO_3^-), and sulfate (SO_4^{2-}). Careful and regular monitoring of electrolytes and intravenous replacement of fluid and electrolytes are part of the acute care in many illnesses.

Intravenous (IV)—The process of giving a liquid through a vein.

Rehydration—The restoration of water or fluid to a body that has become dehydrated.

Heat exhaustion *see* **Heat disorders**

Heat treatments

Definition

Heat treatments are applications of therapeutic thermal agents to specific body areas experiencing injury or dysfunction.

Purpose

The general purpose of a heat treatment is to increase the extensibility of soft tissues, remove toxins from cells, enhance blood flow, increase function of the tissue cells, encourage muscle relaxation, and help relieve **pain**. There are two types of heat treatments: superficial and deep. Superficial heat treatments apply heat to the outside of the body. Deep heat treatments direct heat toward specific inner tissues through **ultrasound** or by electric current. Heat treatments are beneficial prior to **exercise**, providing a warm-up effect to the soft tissues involved.

Precautions

Heat treatments should not be used on individuals with circulation problems, heat intolerance, or lack of sensation in the affected area. Low blood circulation may contribute to heat-related injuries. Heat treatments also should not be used on individuals afflicted with heart, lung, or kidney diseases. Deep heat treatments should not be used on areas above the eye, heart, or on a pregnant patient. Deep heat treatments over areas with metal surgical implants should be avoided in case of rapid temperature increase and subsequent injury.

Description

There are four different ways to convey heat:

- Conduction is the transfer of heat between two objects in direct contact with each other.
- Conversion is the transition of one form of energy to heat.
- Radiation involves the transmission and absorption of electromagnetic waves to produce a heating effect.
- Convection occurs when a liquid or gas moves past a body part creating heat.

Hot packs, water bottles, and heating pads

Hot packs are a very common form of heat treatment utilizing conduction as a form of heat transfer. Moist heat packs are readily available in most hospitals, **physical therapy** centers, and athletic training rooms. Treatment temperature should not exceed 131°F (55°C). The pack is used over multiple layers of toweling to achieve a comfortable warming effect for approximately 30 minutes. More recently, several manufacturers have developed packs that may be warmed in a microwave over a specified amount of time prior to use.

Hot-water bottles are another form of superficial heat treatment. The bottles are filled half way with hot water between 115–125°F (46.1–52°C). Covered by protective toweling, the hot-water bottle is placed on the treatment area and left until the water has cooled off.

Electrical heating pads continue to be used, however, because of the need for an electrical outlet, safety and convenience become an issue.

Paraffin

Paraffin, a conductive form of superficial heat, is often used for heating uneven surfaces of the body such as the hands. It consists of melted paraffin wax and mineral oil. Paraffin placed in a small bath unit becomes solid at room temperature and is used as a liquid heat treatment when heated at 126–127.4°F (52–53°C). The most common form of paraffin application is called the dip and wax method. In this technique, the patient will dip 8 to 12 times and then the extremity will be covered with a plastic bag and a towel for insulation. Most treatment sessions are about 20 minutes.

Hydrotherapy

Hydrotherapy is used in a form of heat treatment for many musculoskeletal disorders. The hydrotherapy tanks and pools are all generally set at warm temperatures, never exceeding 150°F (65.6°C). Because the patient often performs resistance exercises while in the water, higher water temperatures become a concern as the treatment becomes more physically draining. Because of this, many hydrotherapy baths are now being set at 95–110°F (35–43.3°C). There are also units available with moveable turbine jets, which provide a light massage effect. Hydrotherapy is helpful as a warm-up prior to exercise.

Fluidotherapy

Fluidotherapy is a form of heat treatment developed in the 1970s. It is a dry heat modality consisting of cellulose particles suspended in air. Units come in different sizes and some are restricted to only treating a hand or foot. The turbulence of the gas-solid mixture provides thermal contact with objects that are immersed in the medium. Temperatures of this treatment range from 110–123°F (43.3–50.5°C). Fluidotherapy allows the patient to exercise the limb during the treatment, and also massages the limb, increasing blood flow.

Ultrasound

Ultrasound heat treatments penetrate the body to provide relief to inner tissue. Ultrasound energy comes from the acoustic or sound spectrum and is undetectable to the human ear. By using conducting agents such as gel or mineral oil, the ultrasound transducer warms areas of the musculoskeletal system Some areas of the musculoskeletal system absorb ultrasound better that others. Muscle tissue and other connective tissue such as ligaments and tendons absorb this form of energy very well. However, fat absorbs to a much lesser degree. Ultrasound has a relatively long-lasting effect, continuing up to one hour.

Diathermy

Diathermy is another deep heat treatment. An electrode drum is used to apply heat to an affected area. It consists of a wire coil surrounded by dead space and other insulators such as a plastic housing. Plenty of toweling must be layered between the unit and the patient. This device is unique in that it utilizes the basis of a magnetic field on connective tissues. One advantage of diathermy over various other heat treatments is that fat does resist an electrical field, which is not the case with a magnetic field. It is found to be helpful with those experiencing chronic **low back pain** and **muscle spasms**. Prior to ultrasound technology, diathermy was a popular heat therapy of the 1940s–1960s.

Preparation

Before administering any form of heat treatment, heat sensitivity is accessed and the skin over the affected area is cleansed. When a patient is undergoing any form of heat treatment, supervision should always be present especially in the treatment of hydrotherapy.

Aftercare

Once the heat treatment has been completed, any symptoms of **dizziness** and nausea should be noted and documented along with any skin irritations or discoloring not present prior to the heat treatment. A one hour interval between treatments should be adhered to in order to avoid restriction of blood flow.

Risks

All heat treatments have the potential of tissue damage resulting from excessive temperatures. Proper insulation and treatment duration should be carefully administered for each method. Overexposure during a superficial heat treatment may result in redness, blisters, **burns**, or reduced blood circulation. During ultrasound therapy, excessive treatment over bony areas with little soft tissue (such as hand, feet, and elbow) can cause excessive heat resulting in pain and possible tissue damage. Exposure to the electrode drum during diathermy may produce hot spots.

Heavy metal poisoning

Definition

Heavy metal **poisoning** is the toxic accumulation of heavy metals in the soft tissues of the body.

WWW.BOOKBAZ.IR

Description

Heavy metals are chemical elements that have a specific gravity (a measure of density) at least five times that of water. The heavy metals most often implicated in accidental human poisoning are lead, mercury, arsenic, and cadmium. More recently, thallium has gained some attention in the media as the poison used in several murder cases in the 1990s. Some heavy metals, such as zinc, copper, chromium, iron, and manganese, are required by the body in small amounts, but these same elements can be toxic in larger quantities.

Heavy metals may enter the body in food, water, or air, or by absorption through the skin. Once in the body, they compete with and displace essential **minerals**, such as zinc, copper, magnesium, and **calcium**, and interfere with organ system function. People may come in contact with heavy metals in industrial work, pharmaceutical manufacturing, and agriculture. Children may be poisoned as a result of playing in contaminated soil. **Lead poisoning** in adults has been traced to the use of lead-based glazes on pottery vessels intended for use with food, and contamination of Ayurvedic and other imported herbal remedies. Arsenic and thallium have been mixed with food or beverages to attempt **suicide** or poison others.

Another form of **mercury poisoning** that is seen more and more frequently in the United States is self-injected mercury under the skin. Some boxers inject themselves with mercury in the belief that it adds muscle bulk. Metallic mercury is also used in folk medicine or religious rituals in various cultures. These practices increase the risk of mercury poisoning of children in these ethnic groups or subcultures.

Causes and symptoms

Symptoms will vary, depending on the nature and the quantity of the heavy metal ingested. Patients may complain of nausea, **vomiting**, **diarrhea**, stomach **pain**, **headache**, sweating, and a metallic taste in the mouth. Depending on the metal, there may be blue-black lines in the gum tissues. In severe cases, patients exhibit obvious impairment of cognitive, motor, and language skills. The expression "mad as a hatter" comes from the mercury poisoning prevalent in 17th-century France among hatmakers who soaked animal hides in a solution of mercuric nitrate to soften the hair.

Diagnosis

Heavy metal poisoning may be detected using blood and urine tests, hair and tissue analysis, or x ray. The diagnosis is often overlooked, however, because many of the early symptoms of heavy metal poisoning are nonspecific. The doctor should take a thorough patient history with particular emphasis on the patient's occupation.

In childhood, blood lead levels above 80 ug/dL generally indicate lead poisoning; however, significantly lower levels (>30 ug/dL) can cause intellectual disabilities (ID) and other cognitive and behavioral problems in affected children. The Centers for Disease Control and Prevention considers a blood lead level of 10 ug/dL or higher in children a cause for concern. In adults, symptoms of lead poisoning are usually seen when blood lead levels exceed 80 ug/dL for a number of weeks.

Blood levels of mercury should not exceed 3.6 ug/dL, while urine levels should not exceed 15 ug/dL. Symptoms of mercury poisoning may be seen when mercury levels exceed 20 ug/dL in blood and 60 ug/dL in urine. Mercury levels in hair may be used to gauge the severity of chronic mercury exposure.

Since arsenic is rapidly cleared from the blood, blood arsenic levels may not be very useful in diagnosis. Arsenic in the urine (measured in a 24-hour collection following 48 hours without eating seafood) may exceed 50 ug/dL in people with arsenic poisoning. If acute arsenic or thallium poisoning is suspected, an x ray may reveal these substances in the abdomen (since both metals are opaque to x rays). Arsenic may also be detected in the hair and nails for months following exposure.

Cadmium toxicity is generally indicated when urine levels exceed 10 ug/dL of creatinine and blood levels exceed 5 ug/dL.

Thallium poisoning often causes hair loss (**alopecia**), numbness, and a burning sensation in the skin as well as nausea, vomiting, and **dizziness**. As little as 15–20 mg of thallium per kilogram of body weight is fatal in humans; however, smaller amounts can cause severe damage to the nervous system.

Treatment

When heavy metal poisoning is suspected, it is important to begin treatment as soon as possible to minimize long-term damage to the patient's nervous system and digestive tract. Heavy metal poisoning is considered a medical emergency, and the patient should be taken to a hospital emergency room.

The treatment for most heavy metal poisoning is **chelation therapy**. A chelating agent specific to the

KEY TERMS

Alopecia—Loss of hair.

Chelation—The process by which a molecule encircles and binds to a metal and removes it from tissue.

Heavy metal—One of 23 chemical elements that has a specific gravity (a measure of density) at least five times that of water.

Prussian blue—The common name of potassium ferric hexacyanoferrate, a compound approved in the United States for treatment of thallium poisoning. Prussian blue gets its name from the fact that it was first used by artists in 1704 as a dark blue pigment for oil paints. It has also been used in laundry bluing and fabric printing.

metal involved is given either orally, intramuscularly, or intravenously. The three most common chelating agents are calcium disodium edetate, dimercaprol (BAL), and penicillamine. The chelating agent encircles and binds to the metal in the body's tissues, forming a complex; that complex is then released from the tissue to travel in the bloodstream. The complex is filtered out of the blood by the kidneys and excreted in the urine. This process may be lengthy and painful, and typically requires hospitalization. Chelation therapy is effective in treating lead, mercury, and arsenic poisoning, but is not useful in treating cadmium poisoning. To date, no treatment has been proven effective for cadmium poisoning. Thallium poisoning is treated with a combination of Prussian blue (potassium ferric hexacyanoferrate) and a diuretic because about 35% of it is excreted in the urine; however, if treatment is not started within 72 hours of ingesting the poisoning, damage to the patient's nervous system may be permanent.

In cases of acute mercury, arsenic, or thallium ingestion, vomiting may be induced. **Activated charcoal** may be given in cases of thallium poisoning. Washing out the stomach (gastric lavage) may also be useful. The patient may also require treatment such as intravenous fluids for such complications of poisoning as **shock**, anemia, and kidney failure.

Patients who have taken arsenic, thallium, or mercury in a suicide attempt will be seen by a psychiatrist as part of emergency treatment.

Prognosis

The chelation process can only halt further effects of the poisoning; it cannot reverse neurological damage already sustained.

Prevention

Because arsenic and thallium were commonly used in rat and insect poisons at one time, many countries have tried to lower the rate of accidental poisonings by banning the use of heavy metals in pest control products. Thallium was banned in the United States as a rodent poison in 1984. As a result, almost all recent cases of arsenic and thallium poisoning in the United States were deliberate rather than accidental.

Because exposure to heavy metals is often an occupational hazard, protective clothing and respirators should be provided and worn on the job. Protective clothing should then be left at the work site and not worn home, where it could carry toxic dust to family members. Industries are urged to reduce or replace the heavy metals in their processes wherever possible. Exposure to environmental sources of lead, including lead-based paints, plumbing fixtures, vehicle exhaust, and contaminated soil, should be reduced or eliminated.

People who use Ayurvedic or traditional Chinese herbal preparations as alternative treatments for various illnesses should purchase them only from reliable manufacturers.

Heel spurs

Definition

A heel spur is a bony projection on the sole (plantar) region of the heel bone (also known as the calcaneous). This condition may accompany or result from severe cases of inflammation to the structure called plantar fascia. This associated plantar fascia is a fibrous band of connective tissue on the sole of the foot, extending from the heel to the toes.

Description

Heel spurs are a common foot problem resulting from excess bone growth on the heel bone. The bone growth is usually located on the underside of the heel bone, extending forward to the toes. One explanation for this excess production of bone is a painful tearing of the plantar fascia connected between the toes and heel. This can result in either a heel spur or an inflammation of the plantar fascia, medically termed plantar fascitis. Because this condition is often correlated to a decrease in the arch of the foot, it is more prevalent after the age of six to eight years, when the arch is fully developed.

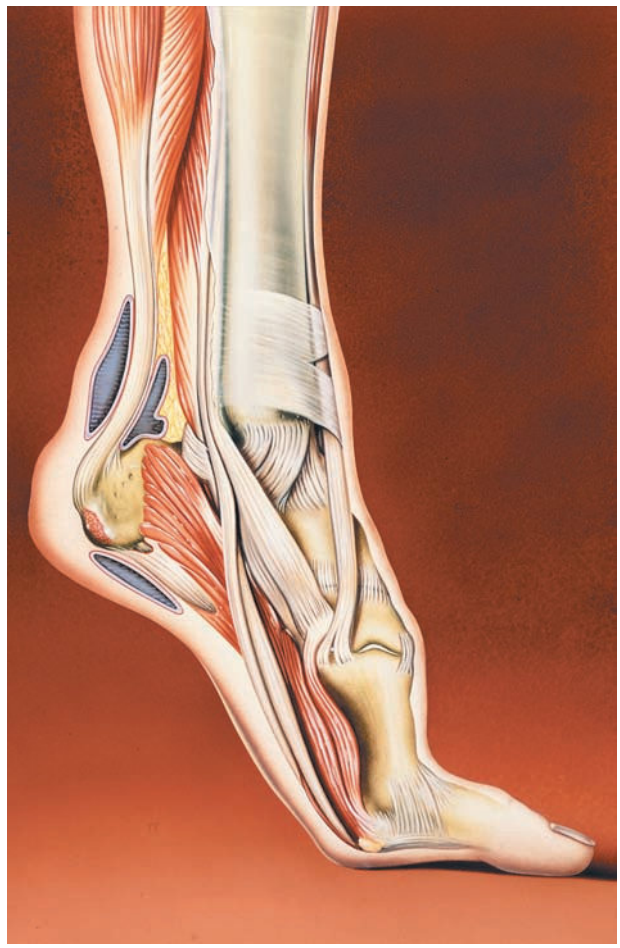

Illustration of a bony projection, a spur, which developed from chronic irritation. *(Photo Researchers, Inc.)*

Causes and symptoms

One frequent cause of heel spurs is an abnormal motion and mal-alignment of the foot called pronation. For the foot to function properly, a certain degree of pronation is required. This motion is defined as an inward action of the foot, with dropping of the inside arch as one plants the heel and advances the weight distribution to the toes during walking. When foot pronation becomes extreme from the foot turning in and dropping beyond the normal limit, a condition known as excessive pronation creates a mechanical problem in the foot. In some cases the sole or bottom of the foot flattens and becomes unstable because of this excess pronation, especially during critical times of walking and athletic activities. The portion of the plantar fascia attached into the heel bone or calcaneous begins to stretch and pull away from the heel bone.

KEY TERMS

Calcaneous—The heel bone.

Genu valgum—Deformity in which the legs are curved inward so that the knees are close together, nearly or actually knocking as a person walks with ankles widely apart of each other.

Plantar fascia—A tough fibrous band of tissue surrounding the muscles of the sole of the foot. Also called plantar aponeurosis.

Pronation—The lowering or descending of the inner edge of the foot by turning the entire foot outwards.

At the onset of this condition, **pain** and swelling become present, with discomfort particularly noted as pushing off with the toes occurs during walking. This movement of the foot stretches the fascia that is already irritated and inflamed. If this condition is allowed to continue, pain is noticed around the heel region because of the newly formed bone, in response to the **stress**. This results in the development of the heel spur. It is common among athletes and others who run and jump a significant amount.

An individual with the lower legs angulating inward, a condition called genu valgum or "knock knees," can have a tendency toward excessive pronation. As a result, this can lead to a fallen arch resulting in plantar fascitis and heel spurs. Women tend to have more genu valgum than men do. Heel spurs can also result from an abnormally high arch.

Other factors leading to heel spurs include a sudden increase in daily activities, an increase in weight, or a change of shoes. Dramatic increase in training intensity or duration may cause plantar fascitis. Shoes that are too flexible in the middle of the arch or shoes that bend before the toe joints will cause an increase in tension in the plantar fascia and possibly lead to heel spurs.

The pain this condition causes forces an individual to attempt walking on his or her toes or ball of the foot to avoid pressure on the heel spur. This can lead to other compensations during walking or running that in turn cause additional problems to the ankle, knee, hip, or back.

Diagnosis

A thorough medical history and physical exam by a physician is always necessary for the proper diagnosis of heel spurs and other foot conditions. X rays of the heel area are helpful, as excess bone production will be visible.

Treatment

Conservative

Heel spurs and plantar fascitis are usually controlled with conservative treatment. Early intervention includes stretching the calf muscles while avoiding reinjuring the plantar fascia. Decreasing or changing activities, losing excess weight, and improving the proper fitting of shoes are all important measures to decrease this common source of foot pain. Modification of footwear includes shoes with a raised heel and better arch support. Shoe orthotics recommended by a healthcare professional are often very helpful in conjunction with exercises to increase strength of the foot muscles and arch. The orthotic prevents excess pronation and lengthening of the plantar fascia and continued tearing of this structure. To aid in this reduction of inflammation, applying ice for 10–15 minutes after activities and use of anti-inflammatory medication can be helpful. **Physical therapy** can be beneficial with the use of heat modalities, such as **ultrasound** that creates a deep heat and reduces inflammation. If the pain caused by inflammation is constant, keeping the foot raised above the heart and/or compressed by wrapping with an ace bandage will help.

Corticosteroid injections are also frequently used to reduce pain and inflammation. Taping can help speed the healing process by protecting the fascia from reinjury, especially during stretching and walking.

Heel surgery

When chronic heel pain fails to respond to conservative treatment, surgical treatment may be necessary. Heel surgery can provide relief of pain and restore mobility. The type of procedure used is based on examination and usually consists of releasing the excessive tightness of the plantar fascia, called a plantar fascia release. Depending on the presence of excess bony build up, the procedure may or may not include removal of heel spurs. Similar to other surgical interventions, there are various modifications and surgical enhancements regarding surgery of the heel.

WWW.BOOKBAZ.IR

Alternatives

Acupuncture and accupressure have been used to address the pain of heel spurs, in addition to using friction massage to help break up scar tissue and delay onset of bony formations.

Prognosis

Usually, heel spurs are curable with conservative treatment. If not, heel spurs are curable with surgery. About 10% of patients that continue to see a physician for plantar fascitis have it for more than a year. If there is limited success after approximately one year of conservative treatment, patients are often advised to have surgery.

Prevention

To prevent this condition, wearing shoes with proper arches and support is very important. Proper stretching is always a necessity, especially when there is an increase in activities or a change in running technique. It is not recommended to attempt working through the pain, as this can change a mild case of heel spurs and plantar fascitis into a long lasting and painful episode of this condition.

The Heimlich maneuver

To perform the Heimlich maneuver on a conscious adult (as illustrated above), the rescuer stands behind the victim and encircles his waist. The rescuer makes a fist with one hand and places the other hand on top, positioned below the rib cage and above the waist. The rescuer then applies pressure by a series of upward and inward thrusts to force the foreign object back up the victim's trachea. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Heimlich maneuver

Definition

The Heimlich maneuver is an emergency procedure for removing a foreign object lodged in the airway that is preventing a person from breathing. It is also known as abdominal thrusts.

Purpose

Each year, between 2,800 and 4,000 adults die in the United States because they accidentally inhale rather than swallow food. The food gets stuck and blocks their trachea (windpipe), making breathing impossible. Death follows rapidly unless the food or other foreign material can be displaced from the airway. This condition is so common it has been nicknamed the "café coronary."

In 1974, Dr. Henry Heimlich first described an emergency technique for expelling foreign material blocking the trachea. This technique, now called the Heimlich maneuver or abdominal thrust, is simple enough that it can be performed immediately by anyone trained in the maneuver. The Heimlich maneuver is a standard part of all **first aid** courses.

The theory behind the Heimlich maneuver is that by compressing the abdomen below the level of the diaphragm, air is forced out of the lungs under pressure. This air dislodges the obstruction in the trachea and brings the foreign material back up into the mouth.

The Heimlich maneuver is used mainly when such solid materials as food, coins, vomit, or small toys are blocking the airway. There has been some controversy about whether the Heimlich maneuver is appropriate to use routinely on near-drowning victims. After several studies of the effectiveness of the Heimlich maneuver on reestablishing breathing in near-drowning victims, the American Red Cross and the American Heart Association both recommend that the Heimlich maneuver be used only as a last resort after traditional airway clearance techniques and **cardiopulmonary resuscitation** (CPR) have been tried repeatedly and failed; or if it is clear that a solid foreign object is blocking the airway.

Demographics

There are no exact statistics on the number of times the Heimlich maneuver is performed in an average year, or the circumstances or age groups of the persons treated, although one study done in California stated that 4% of 513 patients treated for a foreign body in the airway died and that the average age of patients treated was 65. The Heimlich maneuver was the most commonly used intervention, with an 86% success rate.

Description

Anyone can be trained to successfully apply the Heimlich maneuver. Most of the applications each year are provided by trained volunteers. Health professionals may become involved. Paramedics may apply the Heimlich maneuver to a choking person. Physicians, physician assistants and nurses may provide additional treatment in a hospital emergency room. Nurses may provide some follow-up care.

The Heimlich maneuver can be performed on all people. Modifications are necessary if the person **choking** is very obese, pregnant, a child, or an infant. Indications that a person's airway is blocked include:

- inability to speak or cry out
- face turning blue from lack of oxygen
- desperate grabbing at the throat
- weak cough with labored breathing producing a high-pitched noise
- all of the above, followed by unconsciousness

Performing the Heimlich maneuver on adults

To perform the Heimlich maneuver on a conscious adult, the rescuer stands behind the affected person, who may be either sitting or standing. The rescuer makes a fist with one hand and places it, thumb toward the person choking, below the rib cage and above the waist. The rescuer encircles the other person's waist, placing the other hand on top of the fist.

In a series of 6 to 10 sharp and distinct thrusts upward and inward, the rescuer attempts to develop enough pressure to force the foreign object back up the trachea. If the maneuver fails, it is repeated. It is important not to give up if the first attempt fails. As the choking person is deprived of oxygen, the muscles of the trachea relax slightly. Because of this loosening, it is possible that a foreign object may be expelled on a second or third attempt.

If the individual choking is unconscious, the rescuer should place the person supine on the floor; bend the chin forward; make sure the tongue is not blocking the airway; and feel in the mouth for any **foreign objects**, being careful not to push them further into the airway. The rescuer kneels astride the choking person's thighs and places the fists between the bottom of the choking person's breastbone and navel. The rescuer then executes a series of six to 10 sharp compressions by pushing inward and upward.

After the abdominal thrusts, the rescuer repeats the process of lifting the chin, moving the tongue, feeling for and possibly removing any foreign material. If the airway is not clear, the rescuer repeats the abdominal thrusts as often as necessary. If the foreign object has been removed, but the victim is not breathing, the rescuer starts CPR.

Performing the Heimlich maneuver under special circumstances

OBVIOUSLY PREGNANT OR VERY OBESE PEOPLE. The main difference in performing the Heimlich maneuver on this group of people is in the placement of the fists. Instead of using abdominal thrusts, chest thrusts are used. The rescuer's fists are placed against the middle of the breastbone (sternum), and the motion of the chest thrust is in and downward, rather than upward. If the person choking is unconscious, the chest thrusts are similar to those used in CPR.

WWW.BOOKBAZ.IR

CHILDREN. The technique in children over one year of age is the same as in adults, except that the amount of force used is less than that used with adults, in order to avoid damaging a child's ribs, breastbone, and internal organs.

INFANTS UNDER ONE YEAR OLD. The rescuer sits down and positions the infant along the rescuer's forearm with the infant's face pointed toward the floor and at a lower level than the infant's chest. The rescuer's hand supports the infant's head. The forearm rests on the rescuer's own thigh for additional support. Using the heel of the other hand, the rescuer administers four or five rapid blows to the infant's back between the shoulder blades.

After administering the back blows, the rescuer sandwiches the infant between both arms. The infant is turned over so that it lies face up, supported by the rescuer's opposite arm. Using the free hand, the rescuer places the index and middle finger on the center of the breastbone and makes four sharp chest thrusts. This series of back blows and chest thrusts is alternated until the foreign object is expelled.

SELF-ADMINISTRATION OF THE HEIMLICH MANEUVER. To apply the Heimlich maneuver to oneself, a choking person should make a fist with one hand and place it in the middle of the body at a spot above the navel and below the breastbone, then grasp the fist with the other hand and push sharply inward and upward. If this fails, the choking person should press the upper abdomen over the back of a chair, edge of a table, porch railing or something similar, and thrust up and inward until the object is dislodged.

Results

The Heimlich maneuver usually results in the expulsion and removal of an obstruction in the throat; in many situations, the person's life is saved. The choking person suffers no permanent effects from the episode.

Precautions

If possible, have someone nearby call 911 while the rescuer performs the Heimlich maneuver.

It is important to have training and practice in the correct use of the maneuver. Incorrect application of the Heimlich maneuver can damage the chest, ribs, heart, or internal organs of the person on whom it is performed. People may also vomit after being treated with the Heimlich maneuver. It is important to prevent aspiration of the vomitus.

Preparation

Any adult, adolescent, or responsible older child can be trained to perform the Heimlich maneuver. Knowing how to perform it may save someone's life. Before doing the maneuver, it is important to determine whether the airway is completely blocked. If the choking person can talk or cry, the Heimlich maneuver is not appropriate. If the airway is not completely blocked, the choking person should be allowed to try to **cough** up the foreign object without assistance.

Aftercare

Once the obstruction is removed, most persons who experience an episode of choking recover without any further care. Persons who have an obstruction that cannot be dislodged but are able to breathe should be taken to an emergency room for treatment.

Risks

Many people vomit after being treated with the Heimlich maneuver. Depending on the length and severity of the choking episode, the person may need to be taken to a hospital emergency room. In addition, even when the maneuver is performed correctly, the person being treated often has **bruises** in the abdominal area. Occasionally, one or more ribs of the choking person may be broken during administration of the Heimlich maneuver. The elderly are more likely to have bruises or broken ribs during the maneuver than younger adults.

Applying the Heimlich maneuver too vigorously may result in an injury to the internal organs of the choking person. There may be some local **pain** and tenderness at the point where the rescuer's fist was placed. In infants, a rescuer should never attempt to sweep the baby's mouth without looking to remove foreign material. This is likely to push the material farther down the trachea. If the foreign material is not removed, the person choking will die from lack of oxygen.

Research and general acceptance

There is some debate as of 2014 over the benefit of slapping the person's upper back to help dislodge the material in the windpipe. Dr. Heimlich has long maintained that back slaps should not be done because they drive the material deeper into the windpipe. However, the American Red Cross and the American Heart Association presently recommend the use of hard blows with the heel of the rescuer's

KEY TERMS

Aspiration—The entry of body secretions or foreign material into the trachea and lungs.

Diaphragm—The thin layer of muscle that separates the chest cavity, which contains the lungs and heart, from the abdominal cavity, which contains the intestines and digestive organs.

Sternum—The breastbone. The sternum is located over the heart, is the point of attachment for ribs at the front of the body and provides protection to the heart beneath it.

Trachea—The windpipe. A tube extending from below the voice box into the chest where it splits into two branches, the bronchi, that lead to each lung.

hand on the upper back of the victim. The number to be used varies by training organization, but is usually between five and 20. The back slap is designed to create pressure behind the blockage, assisting the patient in dislodging the article in the airway. The Mayo Clinic recommends five back slaps before beginning the abdominal thrusts of the Heimlich maneuver, and alternating between five back blows and five abdominal thrusts until the food or other object is dislodged.

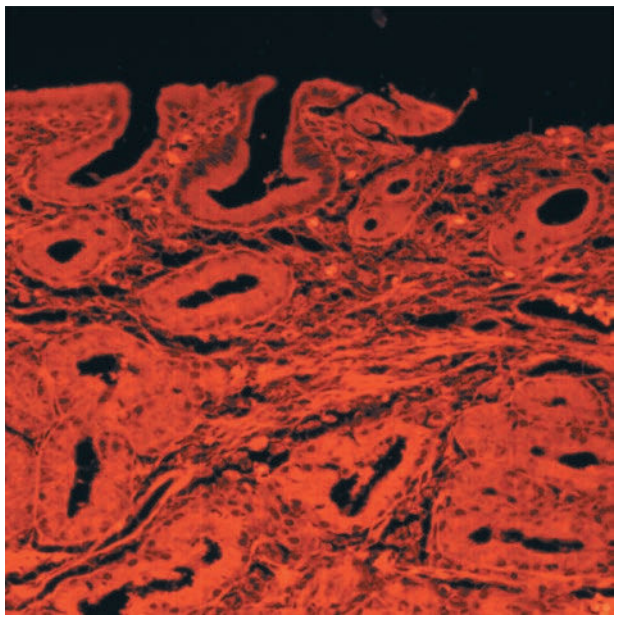
Helicobacter pylori infection *see* **Helicobacteriosis**

Helicobacteriosis

Definition

Helicobacteriosis refers to infection of the gastrointestinal tract with the bacteria, *Helicobacter pylori* (*H. pylori*). While there are other, more rare strains of *Helicobacter* species that can infect humans, only *H. pylori* has been convincingly shown to be a cause of disease in humans. The organism was first documented to cause injury to the stomach in 1983 by two researchers in Australia, who ingested the organism to prove their theory. Since then, *H. pylori* has been shown to be the main cause of ulcer disease, and has revolutionized the treatment

WWW.BOOKBAZ.IR



A light microscopic image of a stomach ulcer. Gastric and duodenal ulcers are usually caused by infection with the bacteria Helicobacter pylori. This bacterium is also believed to be a cause of various cancers of the stomach. *(Custom Medical Stock Photo, Inc.)*

of peptic ulcer disease. It also is believed to be linked to various cancers of the stomach.

Description

H. pylori is a gram-negative, spiral-shaped organism, that contains flagella (tail-like structures) and other properties. In addition to flagella, which help the organism to move around in the liquid mucous layer of the stomach, *H. pylori* also produces an enzyme called urease, that protects it from gastric acid present in the stomach. As the production of this enzyme is relatively unusual, new diagnostic tests have enabled rapid identification of the bacteria.

H. pylori also produces two other chemicals: a cytotoxin called vacA and a protein known as cagA. Patients with ulcer disease are more likely to produce the cytotoxin (vacA). The cagA protein not only occurs frequently in ulcer disease but also in cancer. It is still not known how these substances enable *H. pylori* to cause disease.

Causes and symptoms

Infection with *H. pylori* is largely dependent on two factors; age and income status. The bacteria is acquired mainly in childhood, especially in areas of poor hygiene or overcrowding. *H. pylori* is two to three times more prevalent in developing, non-industrialized countries. In the United States for example, the organism is believed to be present in about one-third of the population.

The exact way in which *H. pylori* gets passed from one individual to another is uncertain, but person to person transmission is most likely. In most cases, children are felt to be the source of spread. Reinfection of those who have been cured has been documented, especially in areas of overcrowding.

The bacteria is well adapted to survival within the stomach. Not only does it survive there for years, but once infection begins, a form of chronic inflammation (chronic **gastritis**) always develops. In most individuals, initial infection causes little or no symptoms; however, some individuals, such as the original researchers who ingested the bacteria, wind up with abdominal **pain** and nausea.

In about 15% of infected persons, ulcer disease develops either in the stomach or duodenum. Why some develop ulcer disease and others do not remains unclear. Ulcer symptoms are characterized by upper abdominal pain that is typically of a burning or "gnawing" type and usually is rapidly relieved by **antacids** or food.

Acid secretion increases in most patients with duodenal **ulcers**. This increase returns to normal once *H. pylori* is eliminated. It is now known that elimination of the bacteria will substantially decrease the risk of recurrent bouts of ulcer disease in the vast majority of patients. In fact, a 2003 report showed that by eradicating *H. pylori*, ulcer bleeding rarely recurs.

In the last decade it has been shown that *H. pylori* is not only the prime cause of ulcer disease of the stomach and duodenum, but is also strongly associated with various tumors of the stomach. Bacterial infection is nine times more common in patients with cancer of the stomach, and seven times more common in those with lymphoma of the stomach (tumor of the lymphatic tissue), called a MALT tumor. It is believed that the prolonged inflammation leads to changes in cell growth and tumors. Eliminating *H. pylori* can lead to regression of some tumors.

In addition, some individuals lose normal gastric function, such as the ability to absorb vitamin B_{12}.

Diagnosis

There are basically two types of tests to identify infection: one group is "invasive" in that it involves

KEY TERMS

Antibiotic—A medication that is designed to kill or weaken bacteria.

Endoscope, Endoscopy—An endoscope as used in the field of gastroenterology is a thin flexible tube that uses a lens or miniature camera to view various areas of the gastrointestinal tract. When the procedure is performed to examine certain organs, such as the bile ducts or pancreas, the organs are not viewed directly, but indirectly through the injection of x ray. The performance of an exam using an endoscope is referred by the general term endoscopy. Diagnosis through biopsies or other means and therapeutic procedures can be done with these instruments.

Gram-negative—Refers to the property of many bacteria in which they do not take or color with Gram's stain, a method used to identify bacteria. Gram-positive bacteria that take up the stain turn purple, while Gram-negative bacteria that do not take up the stain turn red.

the use of an **endoscopy** to obtain biopsy specimens for evaluation, while the other "noninvasive" methods depend on blood or breath samples. Invasive tests can be less accurate because of technical limitations: the biopsy may miss the area where the bacteria hides.

Invasive studies make use of tissue obtained by endoscopic biopsy to identify the organism. The bacteria can be searched for in pieces of biopsy tissue or grown (cultured) from the specimen. However, *H. pylori* is not easy to culture. Another method uses the bacteria's production of the enzyme urease. Biopsy specimens are placed on a card that changes color if urease is present. Results often are available within a few minutes, but can take up to 24 hours.

Noninvasive tests are of two types: blood tests and breath test. Blood tests measure antibodies to make a diagnosis accurately within minutes. This can be done immediately in the doctor's office. In addition, antibody levels can be measured several months after treatment to see if *H. pylori* has been eradicated.

The breath test uses radioactive or non-radioactive forms of a compound called urea, which the patient drinks. The method that uses a radioactive form of urea is easier to perform, as the equipment is commonly available in x ray departments. Radiation exposure is less than that of a chest x ray. The test that uses non-radioactive urea is safer for children. A 2003 study in Brazil showed that the urea breath test and *H. pylori* stool antigen test also worked well to detect the bacteria in children. The breath test is the best way to be sure of elimination of *H. pylori*. The test can be used within 30 days after treatment. This is an advantage over following antibody levels that take six months or longer to diminish.

Treatment

H. pylori peptic ulcers are treated with drugs to kill the bacteria, drugs to reduce stomach acid, and drugs to protect the lining of the stomach. The **antibiotics** most commonly used to kill the bacteria are amoxicillin, clarithromycin, metronidazole, and tetracycline. Drugs used to reduce stomach acid may be histamine blockers or **proton pump inhibitors**. The most commonly used histamine blockers are cimetidine, famotidine, nizatidine, and ranitidine. The most commonly used proton pump inhibitors are lansoprazole and omeprazole. The drug bismuth subsalicylate (a component of Pepto-Bismol) is used to protect the stomach lining.

The most common drug treatment is a two-week course of treatment called triple therapy. This treatment regimen involves taking two antibiotics to kill the bacteria and either an acid reducer or a stomach-lining shield. This therapy has been shown to kill the bacteria, reduce ulcer symptoms, and prevent ulcer recurrence in over 90% of patients.

The main drawback of triple therapy is that some patients find it difficult to follow because it often requires taking as many as 20 pills a day. The antibiotics also may cause unpleasant side effects that may make certain patients less likely to follow the treatment protocol. These side effects include dark stools, **diarrhea**, **dizziness**, **headache**, a metallic taste in the mouth, nausea, **vomiting**, and yeast infections in women.

Prognosis

The elimination of *H. pylori* and cure of ulcer disease is possible in more than 90% of those infected. The finding that most ulcers are due to an infectious agent has brought a dramatic change in treatment and

WWW.BOOKBAZ.IR

outlook for those with the disease. Some patients will wind up with repeated infection, but this is most common in overcrowded areas.

Prevention

Attempts to develop a vaccine to protect against infection may be worthwhile in areas where the *H. pylori* infection rate and occurrence of cancer of the stomach is high. Research has shown such a vaccine would likely be safe in humans, but a vaccine has yet to be fully identified and developed as of 2014.

Hellerwork

Definition

Hellerwork is a system of bodywork that combines deep tissue massage, body movement education, and verbal dialogue. It is designed to realign the body's structure for overall health, improvement of posture, and reduction of physical and mental **stress**.

Purpose

Hellerwork improves posture and brings the body's natural structure into proper balance and alignment. This realignment can bring relief from general aches and pains, improve breathing, and relieve physical and mental stress. Hellerwork has been used to treat such specific physical problems as chronic back, neck, shoulder, and joint **pain** as well as repetitive stress injuries, including **carpal tunnel syndrome**. Hellerwork is also used to treat and prevent athletic injuries.

Description

Origins

Joseph Heller (1940–) developed Hellerwork, a system of structural integration patterned after **Rolfing**. Heller received a degree in engineering and worked for NASA's Jet Propulsion Laboratory in Pasadena, California, before he became interested in humanistic psychology in the 1970s. He spent two years studying bioenergetics and **Gestalt therapy** as well as studying under architect and futurist Buckminster Fuller (1895–1983), flotation tank therapy developer John Lilly, family therapist Virginia Satir, and body movement pioneer Judith Aston.

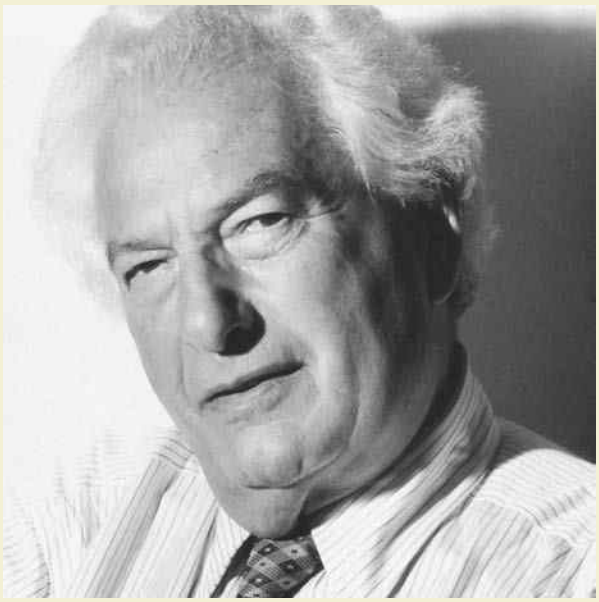
During this period, he trained for six years with Dr. Ida P. Rolf (1896-1979), the founder of Rolfing, and became a certified Rolfer in 1972. After Heller developed his own system of bodywork, he founded Hellerwork in 1979 and established a training facility in Mt. Shasta, California, where he continues his work.

Hellerwork is based largely on the principles of Rolfing, in which the body's connective tissue is manipulated or massaged to realign and balance the body's structure. Because Heller believes that physical realignment is insufficient, he expanded his system to include movement education and verbal dialogue as well as deep tissue massage.

Connective tissue massage

The **massage therapy** aspect of Hellerwork is designed to release the tension that exists in the deep connective tissue, called fascia, and return it to a normal alignment. The fascia is plastic and highly adaptable. It can tighten and harden in response to the general effects of gravity on the body, other ongoing physical stresses, negative attitudes and emotions, and periodic physical traumas. One example of ongoing physical stress is carrying a briefcase, which pulls down the shoulder on one side of the body. Over time, the connective tissue becomes hard and stiff; the body becomes adapted to that position even when the person is not carrying a briefcase. In trying to adjust to the uneven weight distribution, the rest of the body becomes unbalanced and out of proper alignment.

JOSEPH HELLER (1940–)



(AP Images.)

Born in Poland, Joseph Heller attended school in Europe until age 16, when he immigrated to the United States. Living in Los Angeles, he attended the California Institute of Technology in Pasadena and graduated in 1962 with a degree in engineering. He worked for 10 years at the National Aeronautics and Space Administration's Jet Propulsion Laboratory (JPL) in Pasadena as an aerospace engineer. During his service at JPL, Heller became interested in humanistic psychology. After leaving JPL in 1972, he became director of Kairos, a center for human development in Los Angeles. He spent two years studying bioenergetics and gestalt. He also trained under Buckminster Fuller, flotation tank therapy developer John Lilly, self-esteem trainer Virginia Satir, and body movement pioneer Judith Aston.

He became a certified Rolfer in 1972 and spent the next six years studying structural integration under Rolfing founder Ida P. Rolf. He became the first president of the Rolf Institute in 1975. During his training with Rolf, Heller began developing his own system of bodywork. He left the institute in 1978 and moved to Northern California where he founded Hellerwork, which he continues to operate today. According to Hellerwork's website (http://www.hellerwork.com/), his program is a unique and powerful combination of deep-tissue structural integration bodywork, movement education and dialogue. The 11 section series is designed to transform a person's relationship with his body and with the experience of being alive.

Heller believes that as people age, more of these stress and **trauma** patterns become ingrained in the connective tissue, further throwing the body out of alignment. As stress accumulates, the body shortens and stiffens, a process commonly attributed to **aging**. Hellerwork seeks to recondition the body and make the connective tissue less rigid.

Movement education

The second component of Hellerwork, movement education, trains patients in the proper physical movements needed to keep the body balanced and correctly aligned. Movement education focuses on common actions, such as sitting, standing, and walking. Hellerwork practitioners also teach better patterns of movement for activities that are specific to each individual, such as their job and favorite sports or social activities.

Verbal dialogue

Verbal dialogue is the third aspect of Hellerwork. It is designed to teach awareness of the relationships among emotions, life attitudes, and the body. Hellerwork practitioners believe that as patients become responsible for their attitudes, their body movements and patterns of self-expression improve. Dialogue focuses on the theme of each session and the area of the body that is worked on during that session.

Hellerwork consists of 11 90-minute sessions costing about $90–100 each. The first three sessions focus on the surface layers of the fascia and on developmental issues of infancy and childhood. The next four sessions are the core sessions and work on the deep layers and on adolescent developmental issues. The final four treatments are the integrative sessions, and build upon all the previous ones, while also looking at questions of maturity.

Preparations

No advance preparations are required to begin Hellerwork treatment. The treatment is usually done on a massage table with the patient wearing only undergarments.

Precautions

Since Hellerwork involves vigorous deep tissue massage, it is often described as uncomfortable and sometimes painful, especially during the first several

WWW.BOOKBAZ.IR

KEY TERMS

Bioenergetics—A system of therapy that combines breathing and body exercises, psychological therapy, and the free expression of emotions to release blocked physical and psychic energy.

Bodywork—A term that covers a variety of therapies that include massage, realignment of the body, and similar techniques to treat deeply ingrained stresses and traumas carried in the tissues of the body.

Chronic—A disease or condition that progresses slowly but persists or reoccurs over time.

Fascia—The sheet of connective tissue that covers the body under the skin and envelops the muscles and various organs.

Gestalt therapy—A form of therapy that focuses on helping patients reconnect with their bodies and their feelings directly, as contrasted with verbal intellectual analysis.

Kinesiology—The study of the anatomy and physiology of body movement, particularly in relation to therapy.

Rolfing—A deep-tissue therapy that involves manipulating the body's fascia to realign and balance the body's structure.

sessions. As it requires the use of hands, it may be a problem for people who do not like or are afraid of being touched. It is not recommended as a treatment for any disease or a chronic inflammatory condition such as arthritis, and can worsen such a condition. Anyone with a serious medical condition, including **heart disease**, diabetes, or respiratory problems, should consult a medical practitioner before undergoing Hellerwork.

Side effects

There are no reported serious side effects associated with Hellerwork when delivered by a certified practitioner to adults and juveniles.

Research and general acceptance

As with many alternative or holistic treatments, there is little mainstream scientific research documenting the effectiveness of Hellerwork therapy. Since the deep tissue massage aspect of Hellerwork is similar to Rolfing, scientific studies of Rolfing may be useful in evaluating Hellerwork. A 1988 study published in the *Journal of the American Physical Therapy Association* indicated that Rolfing stimulates the parasympathetic nervous system, which can help speed the recovery of damaged tissue. An article in *The Journal of Orthopaedic and Sports Physical Therapy* reported that Rolfing can provide effective and sustained pain relief from lower back problems.

Hematocrit

Definition

The hematocrit measures how much space in the blood is occupied by red blood cells. It is useful when evaluating a person for anemia.

Purpose

Blood is made up of red and white blood cells, and plasma. A decrease in the number or size of red cells also decreases the amount of space they occupy, resulting in a lower hematocrit. An increase in the number or size of red cells increases the amount of space they occupy, resulting in a higher hematocrit. **Thalassemia** is a condition that can cause an increased number of red blood cells but a decreased size and hematocrit.

The hematocrit is usually done on a person with symptoms of anemia. An anemic person has fewer or smaller than normal red cells. A low hematocrit, combined with other abnormal blood tests, confirms the diagnosis.

Some conditions, such as polycythemia, cause an overproduction of red blood cells, resulting in an increased hematocrit.

Transfusion decisions are based on the results of laboratory tests, including hematocrit. Transfusion is not considered if the hematocrit level is reasonable. The level differs for each person, depending on his or her clinical condition.

Description

Blood drawn from a fingerstick is often used for hematocrit testing. The blood fills a small tube, which is then spun in a small centrifuge. As the tube spins, the red blood cells go to the bottom of the tube, the white blood cells cover the red in a thin layer called the buffy coat, and the liquid plasma rises to the top. The spun tube is examined for the line that divides the red cells from the buffy coat and plasma. The height of the red cell column is measured as a percent of the total blood column. The higher the column of red cells, the higher the hematocrit.

The hematocrit test can also be done on an automated instrument as part of a **complete blood count**. It is also called Packed Red Cell Volume or Packed Cell Volume, or abbreviated as Hct or Crit. The test is covered by insurance when medically necessary. Results are usually available the same or following day.

Preparation

To collect the blood by fingerstick, a healthcare worker punctures a finger with a lancet and allows the blood to fill a small tube held to the puncture site.

Tests done on an automated instrument require 5–7 mL of blood. A healthcare worker ties a tourniquet on the person's upper arm, locates a vein in the inner elbow region, and inserts a needle into that vein. Vacuum action draws the blood through the needle into an attached tube. Collection of the sample takes only a few minutes.

KEY TERMS

Anemia—A condition where a person has fewer or smaller than normal red blood cells.

Hemoglobin—The percentage of space in blood occupied by red blood cells.

Aftercare

Discomfort or bruising may occur at the puncture site or the person may feel dizzy or faint. Pressure to the puncture site until the bleeding stops reduces bruising. Warm packs to the puncture site relieve discomfort.

Results

Normal values vary with age and sex. Adult male range is 42–52%, adult female 36–48%.

Abnormal results

Hematocrit values decrease when the size or number of red cells decrease. This is most common in anemia, but other conditions have similar effects: excessive bleeding, damaged cells due to a mechanical heart valve, **liver disease**, and cancers affecting the bone marrow. Additional tests and the person's symptoms and medical history help distinguish these conditions or diagnose a specific type of anemia. Hematocrit values increase when the size or number of red cells increase, such as in polycythemia.

Fluid volume in the blood affects the hematocrit. Pregnant women have extra fluid, which dilutes the blood, decreasing the hematocrit. **Dehydration** concentrates the blood, increasing the hematocrit.

Hemochromatosis

Definition

Hemochromatosis is an inherited blood disorder that causes the body to retain excessive amounts of iron. This iron overload can lead to serious health consequences, most notably **cirrhosis** of the liver.

Description

Hemochromatosis is also known as iron overload, bronze diabetes, hereditary hemochromatosis and familial hemochromatosis. The inherited disorder causes increased absorption of intestinal iron, well beyond that needed to replace the body's loss of iron. Iron overload diseases afflict as many as 1.5 million persons in the United States. The most common of these, as well as one of the most common genetic disorders in the United States, is hereditary hemochromatosis. Men and women are equally affected by hemochromatosis, but women are diagnosed later in life because of blood loss from menstruation and **childbirth**. It most commonly appears in patients between the ages of 40–60 years, since it takes many years for the body to accumulate excessive iron. Symptoms appear later in females than in males—usually after **menopause**.

Hemochromatosis causes excess iron storage in several organs of the body including the liver, pancreas, endocrine glands, heart, skin, joints, and intestinal lining. The buildup of iron in these organs can lead to serious complications, including **heart failure**, **liver cancer**, and cirrhosis of the liver. It is estimated that about 5% of cirrhosis cases are caused by hereditary hemochromatosis.

Idiopathic pulmonary hemosiderosis, a disorder afflicting children and young adults, is a similar overload disorder characterized by abnormal accumulation of hemosiderin. Hemosiderin is a protein found in most tissues, especially the liver. It is produced by digestion of hematin, an iron-related substance.

Hemochromatosis is one of the most common genetic disorders in the United States. Approximately one in nine individuals have one abnormal hemochromatosis gene (11% of the population). Since everyone has two copies of each gene, these individuals have an abnormal *HFE* gene and a normal gene. They are called carriers. Between 1/200 and 1/400 individuals have two abnormal genes for hemochromatosis and no normal gene.

With most autosomal recessive conditions, an affected person's parents are carriers. If more than one family member has the condition, they are siblings. Hemochromatosis is so common, however, that families are seen in which both parents are affected, or one parent is affected and the other parent is a carrier. More than one generation may be affected, which is not usually seen in rare autosomal recessive conditions.

Causes and symptoms

Hereditary hemochromatosis is an autosomal recessive condition. This means that individuals with hemochromatosis have inherited an altered (mutated) gene from both of their parents. Affected individuals have two abnormal hemochromatosis genes and no normal hemochromatosis gene.

The gene that causes hemochromatosis has been identified, and the most common abnormalities of the gene have been described. The gene is on chromosome 6; it is called *HFE*. Scientists have not confirmed the function of the normal gene product; they do know that it interacts with the cell receptor for transferrin. Transferrin binds and transports iron in the blood.

Because it is an autosomal recessive condition, siblings of individuals who have hemochromatosis are at a 25% risk to also be affected. The likelihood that an individual will develop symptoms depends on which gene mutation he or she has as well as environmental factors. The two most common changes in the *HFE* gene are *C282Y* and *H63D*. The age at which symptoms begin is variable, even within the same family.

The symptoms of hemochromatosis include **fatigue**, weight loss, weakness, **shortness of breath**, heart **palpitations**, chronic abdominal **pain**, and impaired sexual performance. The patient may also show symptoms commonly connected with heart failure, diabetes, or cirrhosis of the liver. Changes in the pigment of the skin may appear, such as grayness in certain areas or a tanned or yellow (**jaundice**) appearance. The age of onset and initial symptoms vary.

Idiopathic pulmonary hemosiderosis may first, and only, appear as paleness of the skin. Sometimes the patient will experience spitting of blood from the lungs or bronchial tubes.

Diagnosis

The most common diagnostic methods for hemochromatosis are blood studies of iron, genetic blood studies, **magnetic resonance imaging** (MRI), and **liver biopsy**. Blood studies of transferrin–iron saturation and ferritin concentration are often used to screen

for iron overload. Ferritin is a protein that transports iron and liver enzymes. Additional studies are performed to confirm the diagnosis.

Blood studies used to confirm the diagnosis include additional iron studies and/or genetic blood studies. Genetic blood studies became available in the late 1990s. **Genetic testing** is a reliable method of diagnosis. In 2001 scientists and physicians began to study how accurately having a hemochromatosis mutation predicts whether a person will develop symptoms. Most individuals affected with hemochromatosis (87%) have two identifiable gene mutations; that is, genetic testing will confirm the diagnosis in most individuals. Genetic studies are also be used to determine whether the affected person's family members are at risk for hemochromatosis. The results of genetic testing are the same whether or not a person has developed symptoms.

MRI scans and/or liver biopsy may be necessary to confirm the diagnosis. MRI studies of the liver (or other iron absorbing organs), with quantitative assessment of iron concentration, may reveal abnormal iron deposits. For the liver biopsy, a thin needle is inserted into the liver while the patient is under local **anesthesia**. The needle will extract a small amount of liver tissue, which can be analyzed microscopically to measure its iron content and other signs of hemochromatosis. Diagnosis of idiopathic pulmonary hemosiderosis begins with blood tests and x ray studies of the chest.

Treatment

Patients who show signs of iron overload will often be treated with **phlebotomy**. Phlebotomy is a procedure that involves drawing blood from the patient, just like **blood donation**. Its purpose as a treatment is to rid the body of excess iron storage. Patients may need these procedures one or two times a week for a year or more. Less frequent phlebotomy may be continued in subsequent years to keep excess iron from accumulating. Patients who cannot tolerate phlebotomy due to other medical problems can be treated with Desferal (desferrioxamine). Diet restrictions may be prescribed to limit the amount of iron ingested. Complications from hemochromatosis, such as cirrhosis or diabetes, may also require treatment. Treatment for idiopathic pulmonary hemosiderosis is based on symptoms.

Diet restrictions may help lower the amount of iron in the body, but do not prevent or treat hemochromatosis. Individuals who are affected or who know they have two *C282Y* and/or *H63D* genes may reduce iron intake by avoiding iron and mineral supplements, excess vitamin C, and uncooked seafood. If a patient is symptomatic, he/she may be advised to abstain from drinking alcohol.

Prognosis

With early detection and treatment, the prognosis is usually good. All potential symptoms are prevented if iron levels are kept within the normal range, which is possible if the diagnosis is made before an individual is symptomatic. If a patient is symptomatic but treated successfully before he/she develops liver cirrhosis, the patient's life expectancy is near normal. However, if left untreated, complications may arise that can be fatal. These include liver cancer, liver cirrhosis, **diabetes mellitus**, **congestive heart failure**, and difficulty depleting iron overload through phlebotomy. Liver biopsy can be helpful in determining prognosis of more severely affected individuals. Genetic testing may also be helpful, as variable severity has been noted in patients who have two *C282Y* genes compared to patients with two *H63D* genes or one of each. Men are two times more likely than women to develop severe complications. The prognosis for patients with idiopathic pulmonary hemosiderosis is fair, depending on detection and complications.

Prevention

Screening for hemochromatosis is cost effective, particularly for certain groups of people. Relatives of patients with hemochromatosis—including children, siblings, and parents—should be tested by the most appropriate method. The best screening method may be iron and ferritin studies or genetic testing. If the affected person's diagnosis has been confirmed by genetic testing, relatives may have genetic testing to determine whether or not they have the genetic changes present in the affected individual. Many medical groups oppose genetic testing of children. Relatives who are affected but do not have symptoms can reduce iron intake and/or begin phlebotomy prior to the onset of symptoms, possibly preventing ever becoming symptomatic.

In 2000, population screening for hereditary hemochromatosis was widely debated. Many doctors and scientists wanted population screening because hemochromatosis is easily and cheaply treated, and quite common. Arguments against treatment include the range of symptoms seen (and not seen) with certain gene mutations, and the risk of discrimination in health and life insurance. Whether or not population screening becomes favored by a majority, the

WWW.BOOKBAZ.IR

KEY TERMS

Autosomal—Relating to any chromosome besides the X and Y sex chromosomes. Human cells contain 22 pairs of autosomes and one pair of sex chromosomes.

Cirrhosis—A chronic degenerative disease of the liver, in which normal cells are replaced by fibrous tissue. Cirrhosis is a major risk factor for the later development of liver cancer.

Diabetes mellitus—The clinical name for common diabetes. It is a chronic disease characterized by inadequate production or use of insulin.

Phlebotomy—The taking of blood from the body through an incision in the vein, usually in the treatment of disease.

publicity is beneficial. Hemochromatisis is a common, easily and effectively treated condition. However, diagnosis may be difficult because the presenting symptoms are the same as those seen with many other medical problems. The screening debate has the positive effect of increasing awareness and suspicion of hemochromatisis. Increased knowledge leads to earlier diagnosis and treatment of symptomatic individuals, and increased testing of their asymptomatic at-risk relatives.

Hemoglobin electrophoresis

Definition

Hemoglobin electrophoresis (also called Hgb electrophoresis), is a test that measures the different types of hemoglobin in the blood. The method used is called electrophoresis, a process that causes movement of particles in an electric field, resulting in formation of "bands" that separate toward one end or the other in the field.

Purpose

Hgb electrophoresis is performed when a disorder associated with abnormal hemoglobin (hemoglobinopathy) is suspected. The test is used primarily to diagnose diseases involving these abnormal forms of hemoglobin, such as sickle cell anemia and **thalassemia**.

Precautions

Blood transfusions within the previous 12 weeks may alter test results.

Description

Hemoglobin (Hgb) is comprised of many different types, the most common being A_1, A_2, F, S, and C.

Hgb A_1 is the major component of hemoglobin in the normal red blood cell. Hgb A_2 is a minor component of normal hemoglobin, comprising approximately 2–3% of the total.

Hgb F is the major hemoglobin component in the fetus, but usually exists only in minimal quantities in the normal adult. Levels of Hgb F greater than 2% in

KEY TERMS

Hemoglobin C disease—A disease of abnormal hemoglobin, occurring in 2–3% of African Americans. Only those who have two genes for the disease develop anemia, which varies in severity. Symptoms include episodes of abdominal and joint pain, an enlarged spleen and mild jaundice.

Hemoglobin H disease—A thalassemia-like syndrome causing moderate anemia and red blood cell abnormalities.

Heterozygous—Two different genes controlling a specified inherited trait.

Homozygous—Identical genes controlling a specified inherited trait.

Thalassemias—The name for a group of inherited disorders resulting from an imbalance in the production of one of the four chains of amino acids that make up hemoglobin. Thalassemias are categorized according to the amino acid chain affected. The two main types are alpha-thalassemia and beta-thalassemia. The disorders are further characterized by the presence of one defective gene (thalassemia minor) or two defective genes (thalassemia major). Symptoms vary, but include anemia, jaundice, skin ulcers, gallstones, and an enlarged spleen.

patients over three years of age are considered abnormal.

Hgb S is an abnormal form of hemoglobin associated with the disease of sickle cell anemia, which occurs predominantly in African Americans. A distinguishing characteristic of **sickle cell disease** is the crescent-shaped red blood cell. Because the survival rate of this type of cell is limited, patients with sickle cell disease also have anemia.

Hgb C is another hemoglobin variant found in African Americans. Red blood cells containing Hgb C have a decreased life span and are more readily destroyed than normal red blood cells, resulting in mild to severe **hemolytic anemia**.

Each of the major hemoglobin types has an electrical charge of a different degree, so the most useful method for separating and measuring normal and abnormal hemoglobins is electrophoresis. This process involves subjecting hemoglobin components from dissolved red blood cells to an electric field. The components then move away from each other at different rates, and when separated form a series of distinctly pigmented bands. The bands are then compared with those of a normal sample. Each band can be further assessed as a percentage of the total hemoglobin, indicating the severity of any abnormality.

Preparation

This test requires a blood sample. No special preparation is needed before the test.

Risks

Risks for this test are minimal, but may include slight bleeding from the blood-drawing site, **fainting** or feeling lightheaded after venipuncture, or hematoma (blood accumulating under the puncture site).

Results

Normal reference values can vary by laboratory, but are generally within the following ranges.

Adults:

- Hgb A_1: 95–98%
- Hgb A_2: 2–3%
- Hgb F: 0.8–2%
- Hgb S: 0%
- Hgb C: 0%.

Child (Hgb F):

- 6 months: 8%
- greater than 6 months: 1–2%
- newborn (Hgb F): 50–80%

Abnormal results

Abnormal reference values can vary by laboratory, but when they appear within these ranges, results are usually associated with the conditions that follow in parentheses.

Hgb A_2:

- 4–5.8% (β-thalassemia minor)
- under 2% (Hgb H disease)

Hgb F:

- 2–5% (β-thalassemia minor)
- 10–90% (β-thalassemia major)
- 5–35% (Heterozygous hereditary persistence of fetal hemoglobin, or HPFH)
- 100% (Homozygous HPFH)
- 15% (Homozygous Hgb S)

WWW.BOOKBAZ.IR

Homozygous Hgb S:

• 70–98% (Sickle cell disease).

Homozygous Hgb C:

• 90–98% (Hgb C disease)

Hemoglobin test

Definition

Hemoglobin is a protein inside red blood cells that carries oxygen throughout the body. A hemoglobin test reveals how much hemoglobin is in a person's blood, helping to diagnose and monitor anemia and **polycythemia vera**.

Purpose

A hemoglobin test is done when a person is ill or during a general **physical examination**. Good health requires an adequate amount of hemoglobin. The amount of oxygen in the body tissues depends on how much hemoglobin is in the red cells. Without enough hemoglobin, the tissues lack oxygen and the heart and lungs must work harder to try to compensate.

If the test indicates a "less than" or "greater than" normal amount of hemoglobin, the cause of the decrease or increase must be discovered. A low hemoglobin usually means the person has anemia. Anemia results from conditions that decrease the number or size of red cells, such as excessive bleeding, a dietary deficiency, destruction of cells because of a **transfusion** reaction or mechanical heart valve, or an abnormally formed hemoglobin.

A high hemoglobin may be caused by polycythemia vera, a disease in which too many red blood cells are made.

Hemoglobin levels also help determine if a person needs a blood transfusion. Usually a person's hemoglobin must be below 8 gm/dL before a transfusion is considered.

Description

Hemoglobin is made of heme, an iron compound, and globin, a protein. The iron gives blood its red color. Hemoglobin tests make use of this red color. A chemical is added to a sample of blood to make the red blood cells burst. When they burst, the red cells release hemoglobin into the surrounding fluid, coloring it clear red. By measuring the color using an instrument called a spectrophotometer, the amount of hemoglobin is determined.

Hemoglobin is often ordered as part of a **complete blood count** (CBC), a test that includes other blood cell measurements.

Some people inherit hemoglobin with an abnormal structure. These abnormal hemoglobins cause diseases, such as sickle cell or Hemoglobin C disease. Special tests, using a process called **hemoglobin electrophoresis**, identify abnormal hemoglobins.

Preparation

This test requires 5 mL of blood. A healthcare worker ties a tourniquet on the person's upper arm, locates a vein in the inner elbow region, and inserts a needle into that vein. Vacuum action draws the blood through the needle into an attached tube. Collection of the sample takes only a few minutes.

The person should avoid **smoking** before this test as smoking can increase hemoglobin levels.

Aftercare

Discomfort or bruising may occur at the puncture site or the person may feel dizzy or faint. Pressure to the puncture site until the bleeding stops reduces bruising. Warm packs to the puncture site relieve discomfort.

Results

Normal values vary with age and sex. Women generally have lower hemoglobin values than men. Men have 14.0–18.0 g/dL, while women have levels of 12.0–16.0 g/dL.

Abnormal results

A low hemoglobin usually indicates the person has anemia. Further tests are done to discover the

KEY TERMS

Anemia—A condition characterized by a decrease in the size or number of red blood cells.

Hemoglobin—A protein inside red blood cells that carries oxygen to body tissues.

Polycythemia vera—A disease in which the bone marrow makes too many red blood cells.

cause and type of anemia. Dangerously low hemoglobin levels put a person at risk of a **heart attack**, **congestive heart failure**, or **stroke**.

A high hemoglobin indicates the body is making too many red cells. Further tests are done to see if this is caused by polycythemia vera or as a reaction to illness, high altitudes, **heart failure**, or lung disease.

Fluid volume in the blood affects hemoglobin values. Pregnant women and people with **cirrhosis** have extra fluid, which dilutes the blood, decreasing the hemoglobin. **Dehydration** concentrates the blood, increasing the hemoglobin.

Hemoglobinopathies

Definition

Hemoglobinopathies are genetic (inherited) disorders of hemoglobin, the oxygen-carrying protein of the red blood cells.

Description

The hemoglobin molecule is composed of four separate polypeptide chains of amino acids, two alpha chains, and two beta chains, as well as four iron-bearing heme groups that bind oxygen. The alpha chains are coded for by two similar genes on chromosome 16; the beta chains by a single gene on chromosome 11. Mutations and deletions in these genes cause one of the many hemoglobinopathies.

In general, hemoglobinopathies are divided into those in which the gene abnormality results in a qualitative change in the hemoglobin molecule and those in which the change is quantitative. Sickle cell anemia (**sickle cell disease**) is the prime example of the former, and the group of disorders known as the **thalassemias** constitute the latter. It has been estimated that 333,000 people worldwide are seriously affected by one of these genetic disorders.

Causes and symptoms

Sickle cell anemia (SSA), an autosomal recessive disorder more common in the Black population, is caused by a single mutation in the gene that codes for the beta polypeptide. Approximately 1:400 to 1:600 African Americans are born with the disorder, and, one in 10 is a carrier of one copy of the mutation. In certain parts of the African continent, the prevalence of the disease reaches 1:50 individuals.

The sickle cell mutation results in the substitution of the amino acid valine for glutamic acid in the sixth position of the beta polypeptide. In turn, this alters the conformation of the hemoglobin molecule and causes the red blood cells to assume a characteristic sickle shape under certain conditions. These sickle-shaped cells, no longer able to pass smoothly through small capillaries, can block the flow of blood. This obstruction results in symptoms including growth retardation, severe **pain** crises, tissue and organ damage, splenomegaly, and strokes. Individuals with SSA are anemic and prone to infections, particularly **pneumonia**, a significant cause of death in this group. Some or all of these symptoms are found in individuals who have the sickle mutation in both copies of their beta-globin gene. Persons with one abnormal gene and one normal gene are said to be carriers of the sickle cell trait. Carriers are unaffected because of the remaining normal copy of the gene.

The thalassemias are a diverse group of disorders characterized by the fact that the causative mutations result in a decrease in the amount of normal hemoglobin. Thalassemias are common in Mediterranean populations as well as in Africa, India, the Mideast, and Southeast Asia. The two main types of thalassemias are alpha-thalassemia due to mutations in the alpha polypeptide and beta-thalassemia resulting from beta chain mutations.

Since individuals possess a total of four genes for the alpha polypeptide (two genes on each of their two

WWW.BOOKBAZ.IR

chromosomes 16), disease severity depends on how many of the four genes are abnormal. A defect in one or two of the genes has no clinical effect. Abnormalities of three results in a mild to moderately severe anemia (hemoglobin H disease) and splenomegaly. Loss of function of all four genes usually causes such severe oxygen deprivation that the affected fetus does not survive. A massive accumulation of fluid in the fetus (hydrops fetalis) results in **stillbirth** or neonatal death.

Beta thalassemias can range from mild and clinically insignificant (beta **thalassemia** minor) to severe and life-threatening (beta thalassemia major, also known as Cooley's anemia), depending on the exact nature of the gene mutation and whether one or both copies of the beta gene are affected. While the milder forms may only cause slight anemia, the more severe types result in growth retardation, skeletal changes, splenomegaly, vulnerability to infections, and death as early as the first decade of life.

Diagnosis

Many countries, including the United States, have made concerted efforts to screen for sickle cell anemia at birth because of the potential for beginning early treatment and counseling parents about their carrier status. Diagnosis is traditionally made by blood tests, including **hemoglobin electrophoresis**. Similar tests are used to determine whether an individual is a sickle cell or thalassemia carrier. In certain populations with a high prevalence of one of the mutations, carrier testing is common. If both members of a couple are carriers of one of these conditions, it is possible through prenatal **genetic testing** to determine if the fetus will be affected, although the severity of the disease cannot always be predicted.

Treatment

Treatment of SSA has improved greatly in recent years with a resulting increase in life expectancy. The use of prophylactic (preventative) antibiotic therapy has been particularly successful. Other treatments include fluid therapy to prevent **dehydration**, oxygen supplementation, pain relievers, blood transfusions, and several different types of medications. Recent interest has focused on **bone marrow transplantation**, which has been successful in selected patients.

Since the clinically important thalassemias are characterized by severe anemia, the traditional treatment has been blood **transfusion**, but the multiple transfusions needed to sustain life lead to an iron overload throughout the tissues of the body and eventual destruction of the heart and other organs. For this reason, transfusion therapy must also include infusions of medications such as deferoxamine (desferroxamine) to rid the body of excess iron. **Phlebotomy** is another technique that has been used with some success to lower the concentration of iron in the patient's blood. As with sickle cell anemia, bone marrow therapy has been successful in some cases.

Until very recently, patients being treated with bone marrow transplants had to find a sibling or other closely related donor in order to avoid rejection of the transplant. Advances in the preparation of the transplanted cells, however, have made the use of bone marrow from unrelated donors (URD) an option for patients with hemoglobinopathies. The National Marrow Donor Program reports that about 40% of bone marrow transplants involve a patient in the United States receiving marrow from an international donor or an international patient receiving marrow from a donor in the United States.

Emphasis is also being placed on developing drugs that treat SSA directly. The most promising of these drugs is hydroxyurea, a drug that was originally designed for anticancer treatment. Hydroxyurea has been shown to reduce the frequency of painful crises and acute chest syndrome in adults, and to lessen the need for blood transfusions. Hydroxyurea seems to work by inducing a higher production of fetal hemoglobin. The major side effects of the drug include decreased production of platelets, red blood cells, and certain white blood cells. The effects of long-term hydroxyurea treatment are unknown; however, a nine-year follow-up study of 299 adults with frequent painful crises reported in 2003 that taking hydroxyurea was associated with a 40% reduction in mortality.

Another promising development for the treatment of hemoglobinopathies is **gene therapy** SSA. In late 2001, genetic scientists reported that they had designed a gene that might lead to a future treatment of sickle cell anemia. Although the gene had not been tested in humans, early results showed that the injected gene protected cells from sickling. Experiments in gene therapy for sickle cell disease have been carried out in mice, using lentiviral vectors to transfer the corrective gene into the mouse's stem cells. This technique, however, has not yet been attempted in human subjects.

Prognosis

Hemoglobinopathies are life-long disorders. The prognosis depends upon the exact nature of the mutation and the availability of effective treatment, as well as the individual's compliance with therapies.

KEY TERMS

Amino acids—Organic compounds that form the building blocks of protein. There are 20 different amino acids.

Autosomal recessive—A pattern of inheritance in which both copies of an autosomal gene must be abnormal for a genetic condition or disease to occur. An autosomal gene is a gene that is located on one of the autosomes or non-sex chromosomes. When both parents have one abnormal copy of the same gene, they have a 25% chance with each pregnancy that their offspring will have the disorder.

Hemoglobin—Protein-iron compound in the blood that carries oxygen to the cells and carries carbon dioxide away from the cells.

Hydroxyurea—A drug that has been shown to induce production of fetal hemoglobin. Fetal hemoglobin has a pair of gamma-globin molecules in place of the typical beta-globins of adult hemoglobin. Higher-than-normal levels of fetal hemoglobin can prevent sickling from occurring.

Phlebotomy—Drawing blood from a vein for diagnosis or treatment. Phlebotomy is sometimes used in the treatment of hemoglobinopathies to lower the iron concentration of the blood.

Sickle cell—A red blood cell that has assumed an elongated shape due to the presence of hemoglobin S.

Splenomegaly—Enlargement of the spleen.

Hemoglobinopathies significantly complicate **pregnancy** and increase the risk of infant mortality.

Prevention

Because the hemoglobinopathies are inherited diseases, primary prevention involves carriers making reproductive decisions to prevent passage of the abnormal gene to their offspring. At present, most prevention is targeted toward the symptoms using known treatments.

Hemolytic anemia

Definition

Red blood cells have a normal life span of approximately 90–120 days, at which time the old cells are destroyed and replaced by the body's natural processes. Hemolytic anemia is a disorder in which the red blood cells are destroyed prematurely. The cells

WWW.BOOKBAZ.IR

are broken down at a faster rate than the bone marrow can produce new cells. Hemoglobin, the component of red blood cells that carries oxygen, is released when these cells are destroyed.

Description

As a group, **anemias** (conditions in which the number of red blood cells or the amount of hemoglobin in them is below normal) are the most common blood disorders. Hemolytic anemias, which result from the increased destruction of red blood cells, are less common than anemias caused by excessive blood loss or by decreased hemoglobin or red cell production.

Since a number of factors can increase red blood cell destruction, hemolytic anemias are generally identified by the disorder that brings about the premature destruction. Those disorders are classified as either inherited or acquired. Inherited hemolytic anemias are caused by inborn defects in components of the red blood cells—the cell membrane, the enzymes, or the hemoglobin. Acquired hemolytic anemias are those that result from various other causes. With this type, red cells are produced normally, but are prematurely destroyed because of damage that occurs to them in the circulation.

Causes and symptoms

Inherited hemolytic anemias involve conditions that interfere with normal red blood cell production. Disorders that affect the red blood cell membrane include hereditary spherocytosis, in which the normally disk-shaped red cells become spherical, and hereditary elliptocytosis, in which the cells are oval, rather than disk-shaped. Other hereditary conditions that cause hemolytic anemia include disorders of the hemoglobin, such as sickle cell anemia and **thalassemia**, and red blood cell enzyme deficiencies, such as G6PD deficiency.

The causes of acquired hemolytic anemias vary, but the most common are responses to certain medications and infections. Medications may cause the body to develop antibodies that bind to the red blood cells and cause their destruction in the spleen. Immune hemolytic anemia most commonly involves antibodies that react against the red blood cells at body temperature (warm-antibody hemolytic anemia), which can cause premature destruction of the cells. About 20% of hemolytic anemias caused by warm antibodies come from diseases such as lymphocytic leukemia, 10% from an autoimmune disease, and others are drug-induced. Cold-antibody hemolytic anemia is a condition in which the antibodies react with the red blood cells at a temperature below that of normal body temperature. Red blood cells can also receive mechanical damage as they circulate through the blood vessels. Aneurysms, artificial heart valves, or very high blood pressure can cause the red cells to break up and release their contents. In addition, hemolytic anemia may be caused by a condition called **hypersplenism**, in which a large, overactive spleen rapidly destroys red blood cells.

Major symptoms of hemolytic anemias are similar to those for all anemias, including **shortness of breath**; noticeable increase in heart rate, especially with exertion; **fatigue**; pale appearance; and dark urine. A yellow tint, or **jaundice**, may be seen in the skin or eyes of hemolytic anemia patients. Examination may also show an enlarged spleen. A more emergent symptom of hemolytic anemia is **pain** in the upper abdomen. Severe anemia is indicated if there are signs of **heart failure** or an enlarged liver.

Diagnosis

In order to differentiate hemolytic anemia from others, physicians will examine the blood for the number of young red blood cells, since the number of young cells is increased in hemolytic anemia. The physician will also examine the abdominal area to check for spleen or liver enlargement. If the physician knows the duration of hemolysis, it may also help differentiate between types of anemia. There are a number of other indications that can be obtained from blood samples that will help a physician screen for hemolytic anemia. An antiglobulin (Coomb's) test may be performed as the initial screening exam after determining hemolysis. In the case of immune hemolytic anemia, a direct Coomb's test is almost always positive.

Treatment

Treatment will depend on the cause of the anemia and may involve treatment of the underlying cause. If the hemolytic anemia was brought on by hereditary spherocytosis, the spleen may be removed. Corticosteroid medications, or adrenal **steroids**, may be effective, especially in hemolytic anemia due to antibodies. If the cause of the disorder is a medication, the medication should be stopped. When anemia is severe in conditions such as sickle cell anemia and thalassemia, blood transfusions may be indicated.

Prognosis

Hemolytic anemias are seldom fatal. However, if left untreated, hemolytic anemia can lead to heart failure or liver complications.

KEY TERMS

Antibody—Antibodies are parts of the immune system that counteract or eliminate foreign substances or antigens.

Erythrocyte—The name for red blood cells or red blood corpuscles. These components of the blood are responsible for carrying oxygen to tissues and removing carbon dioxide from tissues.

Hemolysis—The process of breaking down red blood cells. As the cells are destroyed, hemoglobin, the component of red blood cells that carries the oxygen, is liberated.

Thalassemia—One of a group of inherited blood disorders characterized by a defect in the metabolism of hemoglobin, or the portion of the red blood cells that transports oxygen throughout the blood stream.

Prevention

Hemolytic anemia due to inherited disorders can not be prevented. Acquired hemolytic anemia may be prevented if the underlying disorder is managed properly.

Teresa Odle

Hemolytic-uremic syndrome

Definition

Hemolytic-uremic syndrome (HUS) is a rare condition that affects mostly children under the age of 10, but also may affect the elderly as well as persons with other illnesses. HUS, which most commonly develops after a severe bowel infection with certain toxic strains of a bacteria, is characterized by destruction of red blood cells, damage to the lining of blood vessel walls, and in severe cases, kidney failure.

Description

Most cases of HUS occur after an infection in the digestive system that has been caused by toxin-producing strains of the bacterium *Escherichia coli*. About 75% of HUS cases in the United States are caused by the strain referred to as *E. coli* O157:H7, which is found in the intestinal tract of cattle, while the remaining cases are caused by non-O157 strains. Some children infected with *E. coli* O157:H7 will develop HUS. HUS also can follow respiratory infection episodes in young children. In the United States, about 20,000 infections and 250 deaths annually are caused by *E. coli* O157:H7. HUS has also been known to occur in persons using drugs such as **oral contraceptives**, immunosuppressors, and antineoplastics and in women during the postpartum period.

E. coli O157:H7, first identified in 1982 and isolated with increasing frequency since then, is found in contaminated foods such as meat, dairy products, and juices. Infection with *E. coli* O157:H7 causes severe **gastroenteritis**, which can include abdominal **pain**, **vomiting**, and bloody **diarrhea**. For most children, the vomiting and diarrhea stop within two to three days. However, about 5–10% of the children will develop HUS and will become pale, tired, and irritable. Toxins produced by the bacteria enter the blood stream, where they destroy red blood cells and platelets, which contribute to the clotting of blood. The damaged red blood cells and platelets clog tiny blood vessels in the kidneys, or form lesions in the kidneys, making it difficult for the kidneys to remove wastes and extra fluid from the body, resulting in **hypertension**, fluid accumulation, and reduced production of urine.

Causes and symptoms

The most common way an *E. coli* O157:H7 infection is contracted is through the consumption of undercooked ground beef (e.g., eating hamburgers that are still pink inside). Healthy cattle carry *E. coli* within their intestines. During the slaughtering process, the meat can become contaminated with the *E. coli* from the intestines. When contaminated beef is ground up, the *E. coli* bacteria are spread throughout the meat. Additional ways to contract an *E. coli* infection include drinking contaminated water and unpasteurized milk and juices, eating contaminated fruits and vegetables, and working with cattle. The infection

WWW.BOOKBAZ.IR

is also easily transmitted from an infected person to others in settings such as day care centers and nursing homes when improper sanitary practices are used.

Symptoms of an *E. coli* O157:H7 infection start about seven days after infection with the bacteria. The first symptom is sudden onset of severe abdominal cramps. After a few hours, watery diarrhea starts, causing loss of fluids and electrolytes (**dehydration**), which causes the person to feel tired and ill. The watery diarrhea lasts for about a day, and then changes to bright red bloody stools, as the infection causes sores to form in the intestines. The bloody diarrhea lasts 2–5 days, with as many as 10 bowel movements a day. Additional symptoms may include **nausea and vomiting**, without a **fever**, or with only a mild fever. After about 5–10 days, HUS can develop, which is characterized by paleness, irritability, and **fatigue**, as well as reduced urine production.

Diagnosis

The diagnosis of an *E. coli* infection is made through a **stool culture**. The culture must be taken within the first 48 hours after the start of the bloody diarrhea. If a positive culture is obtained, the patient should be monitored for the development of HUS, with treatment initiated as required.

Children should not go to day care until they have had two negative stool cultures. Older people in nursing homes should stay in bed until two stool cultures are negative.

Treatment

Treatment of HUS is supportive, with particular attention to management of fluids and electrolytes. Treatment generally is provided in a hospital setting. Blood transfusions may be required. In about 50% of the cases, short term replacement of kidney function is required in the form of dialysis. Most patients will recover kidney function and be able to discontinue dialysis.

Some studies have shown that the use of **antibiotics** and antimotility agents during an *E. coli* infection may worsen the course of the infection and should be avoided. However, other studies have been less definitive. Physicians should stay informed so that clinical practices matches medical advances on this aspect of treatment.

Alternatives

Persons with HUS must be under the care of health care professionals skilled in the treatment of HUS.

KEY TERMS

Antineoplastics—Agents that inhibit or prevent the development, maturation, and proliferation of malignant cells.

Gastroenteritis—An acute inflammation of the lining of the stomach and intestines, characterized by nausea, diarrhea, abdominal pain and weakness, which has various causes, including food poisoning due to infection with such organisms as *Escherichia coli*, *Staphylococcus aureus*, and *Salmonella* species, consumption of irritating food or drink, or psychological factors, such as anger, stress and fear.

Prognosis

Ninety percent of children with HUS who receive careful supportive care survive the initial acute stages of the condition, with most having no long-term effects. However, 10–30% of survivors will have kidney damage that will lead to kidney failure immediately or within several years. The children with kidney failure require on-going dialysis to remove waste and extra fluids from their bodies, or may require a kidney transplant.

Prevention

Prevention of HUS caused by ingestion of foods contaminated with *E. coli* O157:H7 and other toxin-producing bacteria is accomplished through practicing hygienic food preparation techniques, including adequate handwashing, cooking of meat thoroughly, defrosting meats safely, vigorous washing of fruits and vegetables, and handling leftovers properly. Irradiation of meat has been approved by the United States Food and Drug Administration and the United States Department of Agriculture in order to decrease bacterial contamination of consumer meat supplies.

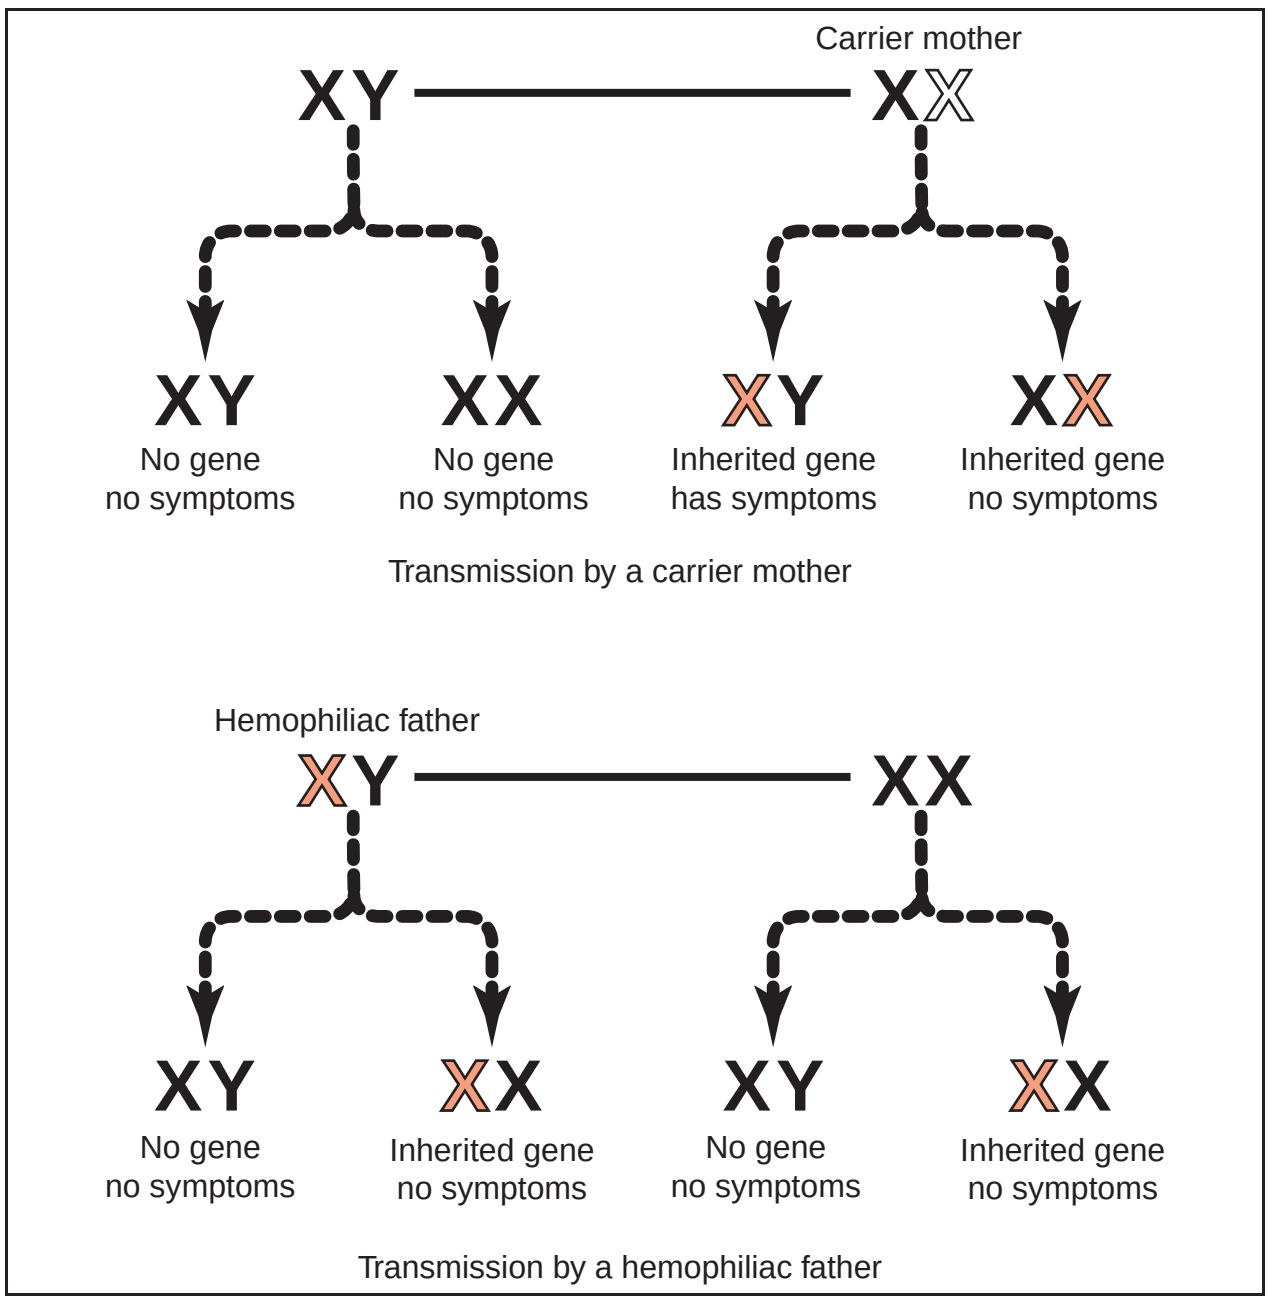
Hemophilia

Definition

Hemophilia is a coagulation disorder arising from a genetic defect of the X chromosome; the defect can either be inherited or result from spontaneous gene mutation. In each type of hemophilia (hemophilias A, B, and C), a critical coagulation protein is missing, causing individuals to bleed for long periods of time before clotting occurs. Depending on the degree of the disorder in the affected individual, uncontrolled bleeding may occur spontaneously with no known initiating event or occur after specific events, such as surgery, dental procedures, immunizations, or injury.



Hemophilia A and B are both caused by a genetic defect present on the X chromosome. Approximately 70% of people with hemophilia A or B inherited the disease, while the remaining 30% have hemophilia due to a spontaneous genetic mutation. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

WWW.BOOKBAZ.IR

Demographics

According to the National Heart, Lung, and Blood Institute (NHLBI), hemophilia affects about 18,000 people in the United States, and each year about 400 babies are born with the disorder, which usually occurs only in males with very rare exceptions. Worldwide, hemophilia A is the most common type of the disorder with about 1 in 4,000 males born with the disorder. As for hemophilia B, it occurs approximately in 1 of 20,000 newborn males. In 2008, an Orphanet report estimated the European prevalence of hemophilia at 7.7 per 100,000 persons. The mortality rate for patients with hemophilia is twice that of the healthy male population. For severe hemophilia, the rate is increased 4–6 times.

Hemophilia A and B are observed in all ethnic and racial groups, with some prevalence reported in Chinese populations.

Description

The normal mechanism for blood clotting is a complex series of events (coagulation cascade) involving interaction between the injured blood vessel, blood cells called platelets, 13 specific coagulation factors (designated by Roman numerals I through XIII), and other substances that circulate in the blood.

When a blood vessel is injured in a way that causes bleeding, platelets collect over the injured area, and form a temporary plug to prevent further bleeding. This temporary plug, however, is too disorganized to serve as a long–term solution, so a series of chemical events occur, resulting in the formation of a more reliable plug. The final plug involves tightly woven fibers of a material called fibrin. The production of fibrin requires the interaction of several chemicals, in particular a series of proteins called clotting factors. At least 13 different clotting factors have been identified.

The clotting cascade, as it is usually called, is the series of events required to form the final fibrin clot. The cascade uses a technique called amplification to rapidly produce the proper sized fibrin clot from the small number of molecules initially activated by the injury.

In hemophilia, certain clotting factors are either decreased in quantity, absent, or improperly formed. Because the clotting cascade uses amplification to rapidly plug up a bleeding area, absence or inactivity of just one clotting factor can greatly increase **bleeding time**.

Hemophilia A is the most common type of bleeding disorder and involves decreased activity of factor VIII. There are three levels of factor VIII deficiency: severe, moderate, and mild. This classification is based on the percentage of normal factor VIII activity present:

- Individuals with less than 1% of normal factor VIII activity level have severe hemophilia. Half of all people with hemophilia A fall into this category. Such individuals frequently experience spontaneous bleeding, most frequently into their joints, skin, and muscles. Surgery or trauma can result in life–threatening hemorrhage and must be carefully managed.
- Individuals with 1–5% of normal factor VIII activity level have moderate hemophilia and are at risk for heavy bleeding after seemingly minor traumatic injury.
- Individuals with 5–40% of normal factor VIII activity level have mild hemophilia, and must prepare carefully for any surgery or dental procedures.

Individuals with hemophilia B have symptoms very similar to those of hemophilia A, but the deficient factor is factor IX. This type of hemophilia is also known as Christmas disease.

Hemophilia C is very rare and is much more mild than hemophilia A or B; it involves factor XI.

Risk factors

Hemophilia is a genetic disorder, which is usually inherited. The hemophilia gene is passed down from a parent to a child. Individuals with a family history of the condition are accordingly at higher risk for hemophilia.

Causes and symptoms

Hemophilia A and B are both caused by a genetic defect present on the X chromosome. (Hemophilia C is inherited in a different fashion.) About 70% of all people with hemophilia A or B inherited the disease. The other 30% develop from a spontaneous genetic mutation.

The following concepts are important to understanding the inheritance of these diseases. All humans have two chromosomes determining their gender: females have XX, males have XY. Because the trait is carried only on the X chromosome, it is called "sex–linked." The chromosome's flawed unit is referred to as the gene.

Both factors VIII and IX are produced by a genetic defect of the X chromosome, so hemophilia A and B are both sex–linked diseases. Because a female child always receives two X chromosomes, she nearly always will receive at least one normal X chromosome. Therefore,

KEY TERMS

Amplification—A process by which something is made larger. In clotting, only a very few chemicals are released by the initial injury; they result in a cascade of chemical reactions that produce increasingly larger quantities of different chemicals, resulting in an appropriately–sized, strong fibrin clot.

Coagulation—Blood clotting.

Coagulation factors—Specific coagulation proteins in the blood required for clotting. Coagulation proteins are designated with Roman numerals I through XIII.

Factors—Coagulation factors are substances in the blood, such as proteins and minerals, that are necessary for clotting. Each clotting substance is designated with Roman numerals I through XIII.

Fibrin—The final substance created through the clotting cascade, which provides a strong, reliable plug to prevent further bleeding from the initial injury.

Hemorrhage—Very severe, massive bleeding that is difficult to control. Hemorrhage can occur in hemophiliacs after what would be a relatively minor injury to a person with normal clotting factors.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Platelets—Small disc–shaped structures that circulate in the blood stream and participate in blood clotting.

Trauma—Injury.

even if she receives one flawed X chromosome, she will still be capable of producing a sufficient quantity of factors VIII and IX to avoid the symptoms of hemophilia. Such a person who has one flawed chromosome, but does not actually have the disease, is called a carrier. She carries the flaw that causes hemophilia and can pass it on to her offspring. If, however, she has a son who receives her flawed X chromosome, he will be unable to produce the right quantity of factors VIII or IX, and he will have some degree of hemophilia. (Males inherit one X and one Y chromosome, and, therefore, have only one X chromosome.)

In rare cases, a hemophiliac father and a carrier mother can pass on the right combination of parental chromosomes to result in a hemophiliac female child. This situation is rare. The vast majority of people with either hemophilia A or B are male.

About 30% of all people with hemophilia A or B are the first member of their family to ever have the disease. These individuals have had the unfortunate occurrence of a spontaneous mutation, meaning that in their early development, some random genetic accident befell their X chromosome, resulting in the defect causing hemophilia A or B. Once such a spontaneous genetic mutation takes place, offspring of the affected person can inherit the newly–created, flawed chromosome.

In the case of severe hemophilia, the first bleeding event usually occurs prior to 18 months of age. In some babies, hemophilia is suspected immediately, when a routine **circumcision** (removal of the foreskin of the penis) results in unusually heavy bleeding. Toddlers are at particular risk, because they fall frequently and may bleed into the soft tissue of their arms and legs. These small bleeds result in bruising and noticeable lumps, but do not usually need treatment. As a child becomes more active, bleeding may occur into the muscles, which is a much more painful and debilitating problem. These muscle bleeds result in **pain** and pressure on the nerves in the area of the bleed. Damage to nerves can cause numbness and decreased ability to use the injured limb.

Some of the most problematic and frequent bleeds occur into the joints, particularly into the knees and elbows. Repeated bleeding into joints can result in scarring within the joints and permanent deformities. Individuals may develop arthritis in joints that have had continued irritation from the presence of blood. Mouth injuries can result in compression of the airway, and can be life–threatening. A blow to the head, which might be totally insignificant in a normal individual, can result in bleeding into the skull and brain. Because the skull has no room for expansion, a person with hemophilia is at risk for brain damage due to blood taking up space and exerting pressure on the delicate brain tissue.

People with hemophilia are at very high risk of hemorrhage (severe, heavy, uncontrollable bleeding) from injuries, such as motor vehicle accidents, and also from surgery.

Some other rare clotting disorders such as **Von Willebrand disease** present similar symptoms but are not usually called hemophilia.

WWW.BOOKBAZ.IR

Diagnosis

Examination

If hemophilia is suspected, or if a person has a bleeding problem, a physician typically takes personal and family medical histories to establish whether the family has a history of frequent or heavy bleeding and bruising.

Tests

Various tests are available to measure, under very carefully controlled conditions, the length of time it takes to produce certain components of the final fibrin clot. The activated **partial thromboplastin time** (APTT) is performed and will typically be prolonged while a **prothrombin time** (PT) will likely be normal. Factor assays, which are measurement methods performed by the clinical laboratory, can determine the percentage of factors VIII and IX present compared to normal percentages. This information helps to confirm a diagnosis of hemophilia and identifies the type and severity of hemophilia present.

Hemophilia A and B are classified as mild, moderate, or severe, depending on the amount of clotting factor VIII or IX in the blood. Mild hemophilia is diagnosed if 5–30% of the normal clotting factors are present. With 1–5% of the normal clotting factors present, the hemophilia is diagnosed as moderate, and as severe when less than 1% of the normal clotting factors are present.

Procedures

Individuals with a family history of hemophilia may benefit from **genetic counseling** before deciding to have a baby. Families with a positive history of hemophilia can also have tests done during a **pregnancy** to determine whether the fetus has hemophilia. A test called chorionic villius sampling examines proteins for the defects that lead to hemophilia. This test, which is associated with a 1% risk of **miscarriage**, can be performed at 10–12 weeks. A test called **amniocentesis** examines the DNA of fetal cells shed into the amniotic fluid for genetic mutations. Amniocentesis, which is associated with a 1 in 200 risk of miscarriage, is performed at 16–18 weeks gestation.

Treatment

Traditional

The most important thing that individuals with hemophilia can do to prevent complications of this disease is to avoid injury. This is accomplished with replacement therapy to replace the clotting factor that is missing or present in low amounts. People with hemophilia are also typically vaccinated against hepatitis.

In replacement therapy, various types of factors VIII and IX are available to replace a patient's missing factors. These are administered intravenously (directly into the patient's veins by needle). Cryoprecipitate, for example, is a single– or multiple–donor human plasma preparation rich in coagulation factors; it is available as a frozen concentrate. Fresh frozen plasma is a single–donor preparation of factor–rich plasma; it is used primarily for replacing factor XI in individuals with hemophilia C. Concentrated factor preparations may be obtained from a single donor by pooling the donations of as many as thousands of donors or by laboratory creation through highly advanced genetic techniques. These preparations are administered directly into the individual's veins (intravenous administration). In 2008, the United States Food and Drug Administration (FDA) approved a new formulation of the genetically engineered version of factor VIIa that can be stored at room temperature for up to two years.

The frequency of treatment with factors depends on the severity of the individual patient's disease. Patients with relatively mild disease will only require treatment in the event of injury, or to prepare for scheduled surgical or dental procedures. Patients with more severe disease will require regular treatment to avoid spontaneous bleeding.

While appropriate treatment of hemophilia can both decrease pain and be life–saving, complications associated with treatment can also be quite serious. About 20% of all patients with hemophilia A begin to produce chemicals in their bodies that rapidly destroy infused factor VIII. The presence of such a chemical may greatly hamper efforts to prevent or stop a major hemorrhage.

Individuals who receive factor prepared from pooled donor blood are at risk for serious infections that may be passed through blood. Hepatitis, a severe and potentially fatal viral liver infection, may be contracted from pooled factor preparations. Recently, concern has been raised about the possibility of hemophiliacs contracting a fatal slow virus infection of the brain (Creutzfeldt–Jakob disease) from blood products. Unfortunately, pooled factor preparations in the early 1980s were contaminated with human **immunodeficiency** virus (HIV), the virus that causes **AIDS**. A large number of

hemophiliacs were infected with HIV and some statistics show that HIV is still the leading cause of death among hemophiliacs. Careful methods of donor testing, as well as methods of inactivating viruses present in donated blood, have greatly lowered this risk.

Drugs

Desmopressin (DDAVP) is a synthetic hormone used in the treatment of mild to moderate hemophilia A. DDAVP is not used to treat hemophilia B or severe hemophilia A. DDAVP usually is given by injection or as a nasal spray. Since it wears off when used often, DDAVP is given only in specific situations. For example, before dental work or before certain physical activities to prevent or reduce bleeding. Antifibrinolytic medicines, such as tranexamic acid and aminocaproic acid, may also be used with replacement therapy. These medications are typically used before dental work or to treat bleeding from the mouth or nose or mild intestinal bleeding.

Medications or drugs that promote bleeding, such as **aspirin**, should be avoided.

Alternatives

New treatments currently being researched involve efforts to transfer new genes to hemophiliacs. These new genes would have the ability to produce the missing factors. As yet, these techniques are not being performed on humans, but there is great hope that eventually this type of **gene therapy** will be available.

Clinical trials for the treatment of hemophilia are currently sponsored by the National Institutes of Health (NIH) and other agencies. In 2009, NIH reported 196 on–going or recently completed studies. Some examples include the following:

- The evaluation of the safety of gene transfer for the treatment of severe hemophilia B. (NCT00076557)
- The study of musculoskeletal function in people with hemophilia in developing countries. (NCT00324493)
- The study of allergic reactions to factor IX in patients with hemophilia B. (NCT00195221)
- A study evaluating inhibitor specificity in hemophilia A. (NCT00151385)

Clinical trial information is constantly updated by NIH and the most recent information on hemophilia trials can be found at: http://clinicaltrials.gov/ct2/results?term = hemophilia

Home remedies

At home, certain steps can help avoid excessive bleeding. They include regular **exercise** to build up muscles and protect joints, avoiding aspirin and nonsteroidal anti–inflammatory drugs (Advil, Motrin, others) that can aggravate bleeding, practicing good dental hygiene to avoid having teeth pulled out, and using protective equipment in sports and physical activities to minimize injuries.

Prognosis

Prognosis is very difficult to generalize. Because there are so many variations in the severity of hemophilia and because much of what befalls a patient will depend on issues such as physical activity level and accidental injuries, statistics on prognosis are not generally available.

Prevention

Because of its genetic origins, hemophilia cannot be prevented in those born with the inherited defects or factor deficiencies. However, individuals who have a family history of hemophilia may benefit from **genetic testing** and counseling before deciding to have a baby. The most important way for individuals with hemophilia to prevent complications of the disease is to avoid activities that may lead to injury. Individuals who require dental work or any type of surgery may need to be pre–treated with an infusion of factor VIII to avoid hemorrhage. Patients with hemophilia should also avoid medications or drugs that promote bleeding; aspirin is one such medication, and many prescription drugs have anticoagulant properties.

Hemophilus ducreyi infection *see* **Chancroid**

Hemophilus infections

Definition

Hemophilus infections, most of which are due to *Haemophilus influenzae* infections, are a group of contagious diseases that are caused by a gram-negative bacterium and affect only humans. Some hemophilus infections are potentially fatal.

Description

H. influenzae is a common organism worldwide; it has been found in the nasal secretions of as many as 90% of healthy individuals in the general population. Hemophilus infections are characterized by acute inflammation with a discharge (exudate). They may affect almost any organ system, but are most common in the respiratory tract. The organism can be transmitted by person-to-person contact or by contact with nasal discharges and other body fluids. Hemophilus infections in the United States are most likely to spread in the late winter or early spring.

The primary factor influencing the rate of infection is age; children between the ages of six months and four years are most vulnerable to *H. influenzae*. In previous years, about 50% of children would acquire a hemophilus infection before reaching one year of age; almost all children would develop one before age three. These figures are declining as a result of the increasing use of hemophilus vaccines for children.

Adults are also susceptible to hemophilus diseases. *H. influenzae pneumonia* is a common nosocomial infection (illnesses contracted in hospitals). The rate of hemophilus infections in the adult population has increased over the past 40 years. The reasons for this change are unclear, but some researchers speculate that the overuse of **antibiotics** has led to the development of drug-resistant strains of *H. influenzae*.

The risk factors for hemophilus infections among adults include:

- smoking
- alcoholism
- chronic lung disease
- old age
- living in a city or institutional housing with a large group of people
- poor nutrition and hygiene
- hIV infection or other immune system disorder

Causes and symptoms

Hemophilus infections are primarily caused by *H. influenzae*, a gram-negative bacterium that is capable of spreading from the nasal tissues and upper airway, where it is usually found, to the chest, throat, or middle ear. The organism sometimes invades localized areas of tissue, producing **meningitis**, **infectious arthritis**, **conjunctivitis**, **cellulitis**, **epiglottitis**, or inflammation of the membrane surrounding the heart. The most serious infections are caused by a strain called *H. influenzae* b (Hib). Before routine **vaccination**, Hib was the most common cause of bacterial meningitis and was responsible for most of the cases of acquired intellectual disabilities (ID) in the United States.

Hemophilus infections in children

BACTERIAL SEPSIS IN THE NEWBORN. Bacterial **sepsis** (the presence of illness-causing microorganisms, or their poisons, in the blood) is a potentially fatal illness in newborn infants. The child may acquire the disease organism as it passes through the mother's birth canal or from the hospital environment. *H. influenzae* can also produce inflammations of the eye (conjunctivitis) in newborn children. The signs of sepsis may include **fever**, crankiness, feeding problems, breathing difficulties, pale or mottled skin, or drowsiness. Premature birth is the most significant risk factor for hemophilus infections in newborns.

EPIGLOTTITIS. Epiglottitis is a potentially fatal hemophilus infection. Although children are more likely to develop epiglottitis, it can occur in adults as well. When the epiglottis (a piece of cartilage behind the tongue which protects the opening to the windpipe by opening and closing) is infected, it can swell to the point where it blocks the windpipe. The symptoms of epiglottitis include a sudden high fever, drooling, the feeling of an object stuck in the throat, and **stridor**. The epiglottis will look swollen and bright red if the doctor examines the patient's throat with a laryngoscope (a viewing device).

MENINGITIS. Meningitis caused by Hib is most common in children between nine months and four years of age. The child usually develops upper respiratory symptoms followed by fever, loss of appetite, **vomiting**, **headache**, and a stiff or sore neck or back. In severe cases, the child may have convulsions or go into **shock** or **coma**.

OTHER INFECTIONS. Hib is the second most common cause of middle ear infection and **sinusitis** in children. The symptoms of sinusitis include fever, **pain**, **bad breath**, and coughing. Children may also develop infectious arthritis from Hib. The joints most frequently affected are the large weight-bearing joints.

Hemophilus infections in adults

PNEUMONIA. Hib **pneumonia** is the most common hemophilus infection in adults. The symptoms include **empyema** (sputum containing pus) and fever. The hemophilus organism can usually be identified from sputum samples. Hib pneumonia is increasingly common in the elderly.

MENINGITIS. Meningitis caused by Hib can develop in adults as a complication of an ear infection or sinusitis. The symptoms are similar to those in children but are usually less severe in adults.

Diagnosis

The diagnosis is usually based on a combination of the patient's symptoms and the results of blood counts, cultures, or antigen detection tests.

Laboratory tests

Laboratory tests can be used to confirm the diagnosis of hemophilus infections. The bacterium can be grown on chocolate agar or identified by blood cultures or Gram stain of body fluids. Antigen detection tests can be used to identify hemophilus infections in children. These tests include latex agglutination and electrophoresis.

Other laboratory findings that are associated with hemophilus infections include anemia (low red blood cell count) and a drop in the number of white blood cells in children with severe infections. Adults often show an abnormally high level of white blood cells; cell counts of 15,000–30,000/mm^3 are not unusual.

Treatment

Because some hemophilus infections are potentially fatal, treatment is started without waiting for the results of laboratory tests.

WWW.BOOKBAZ.IR

KEY TERMS

Bacterium—A microscopic one-celled organism. *Haemophilus influenzae* is a specific bacterium.

Epiglottitis—Inflammation of the epiglottis. The epiglottis is a piece of cartilage behind the tongue that closes the opening to the windpipe when a person swallows. An inflamed epiglottis can swell and close off the windpipe, causing the patient to suffocate.

Exudate—A discharge produced by the body. Some exudates are caused by infections.

Gram-negative—A term that means that a bacterium will not retain the violet color when stained with Gram's dye. *Haemophilus influenzae* is a gram-negative bacterium.

Intubation—The insertion of a tube into the patient's airway to protect the airway from collapsing. Intubation is sometimes done as an emergency procedure for patients with epiglottitis.

Nosocomial—Contracted in a hospital. Pneumonia caused by *H. influenzae* is an example of a nosocomial infection.

Sepsis—Invasion of body tissues by disease organisms or their toxins. Sepsis may be either localized or generalized. *H. influenzae* can cause bacterial sepsis in newborns.

Stridor—A harsh or crowing breath sound caused by partial blockage of the patient's upper airway.

Tracheotomy—An emergency procedure in which the surgeon cuts directly through the patient's neck into the windpipe in order to keep the airway open.

Medications

Hemophilus infections are treated with antibiotics. Patients who are severely ill are given ampicillin or a third-generation cephalosporin, such as cefotaxime or ceftriaxone, intravenously. Patients with milder infections are given oral antibiotics, including amoxicillin, cefaclor, erythromycin, or trimethoprim-sulfamethoxazole. Patients who are allergic to penicillin are usually given cefaclor or trimethoprim-sulfamethoxazole.

Patients with Hib strains that are resistant to ampicillin may be given chloramphenicol. Chloramphenicol is not a first-choice drug because of its side effects, including interference with bone marrow production of blood cells.

The duration of antibiotic treatment depends on the location and severity of the hemophilus infection. Adults with respiratory tract infections, or Hib pneumonia, are usually given a 10–14 day course of antibiotics. Meningitis is usually treated for 10–14 days, but a seven-day course of treatment with ceftriaxone appears to be sufficient for infants and children. Ear infections are treated for 7–10 days.

Supportive care

Patients with serious hemophilus infections require bed rest and a humidified environment (such as a **croup** tent) if the respiratory tract is affected. Patients with epiglottitis frequently require intubation (insertion of a breathing tube) or a **tracheotomy** to keep the airway open. Patients with inflammation of the heart membrane, pneumonia, or arthritis may need surgical treatment to drain infected fluid from the chest cavity or inflamed joints.

Supportive care also includes monitoring of blood cell counts for patients using chloramphenicol, ampicillin, or other drugs that may affect production of blood cells by the bone marrow.

Prognosis

The most important factors in the prognosis are the severity of the infection and promptness of treatment. Untreated hemophilus infections—particularly meningitis, sepsis, and epiglottitis—have a high mortality rate. Bacterial sepsis of the newborn has a mortality rate between 13% and 50%. The prognosis is usually good for patients with mild infections who are treated without delay. Children who develop Hib arthritis sometimes have lasting problems with joint function.

Prevention

Hemophilus vaccines

There are three different vaccines for hemophilus infections used to immunize children in the United States: PRP-D, HBOC, and PRP-OMP. PRP-D is used only in children older than 15 months. HBOC is administered to infants at two, four, and six months after birth, with a booster dose at 15–18 months. PRP-OMP is administered to infants at two and four months, with the third dose at the child's first birthday. All three vaccines are given by intramuscular

injection. About 5% of children may develop a fever or soreness in the area of the injection.

Other measures

Other preventive measures include isolating patients with respiratory hemophilus infections; treating appropriate contacts of infected patients with rifampin; maintaining careful standards of cleanliness in hospitals, including proper disposal of soiled tissues; and washing hands properly.

Hemoptysis

Definition

Hemoptysis is the coughing up of blood or bloody sputum from the lungs or airway. It may be either self-limiting or recurrent. Massive hemoptysis is defined as 200–600 mL of blood coughed up within a period of 24 hours or less.

Description

Hemoptysis can range from small quantities of bloody sputum to life-threatening amounts of blood. The patient may or may not have chest **pain**.

Causes and symptoms

Hemoptysis can be caused by a range of disorders:

- Infections. These include pneumonia; tuberculosis; aspergillosis; and parasitic diseases, including ascariasis, amebiasis, and paragonimiasis.
- Tumors that erode blood vessel walls.
- Drug abuse. Cocaine can cause massive hemoptysis.
- Trauma. Chest injuries can cause bleeding into the lungs.
- Vascular disorders, including aneurysms, pulmonary embolism, and malformations of the blood vessels.
- Bronchitis. Its most common cause is long-term smoking.
- Foreign object(s) in the airway.
- Blood clotting disorders.
- Bleeding following such surgical procedures as bronchial biopsies and heart catheterization.

Diagnosis

The diagnosis of hemoptysis is complicated by the number of possible causes.

Patient history

It is important for the doctor to distinguish between blood from the lungs and blood coming from the nose, mouth, or digestive tract. Patients may aspirate, or breathe, blood from the nose or stomach into their lungs and **cough** it up. They may also swallow blood from the chest area and then vomit. The doctor will ask about stomach **ulcers**, repeated **vomiting**, **liver disease**, **alcoholism**, **smoking**, **tuberculosis**, mitral valve disease, or treatment with anticoagulant medications.

Physical examination

The doctor will examine the patient's nose, throat, mouth, and chest for bleeding from these areas and for signs of chest **trauma**. The doctor also listens to the patient's breathing and heartbeat for indications of heart abnormalities or lung disease.

Laboratory tests

Laboratory tests include blood tests to rule out clotting disorders, and to look for food particles or other evidence of blood from the stomach. Sputum can be tested for fungi, bacteria, or parasites.

X ray and bronchoscopy

Chest x rays and **bronchoscopy** are the most important studies for evaluating hemoptysis. They are used to evaluate the cause, location, and extent of the bleeding. The bronchoscope is a long, flexible tube used to identify tumors or remove **foreign objects**.

Imaging and other tests

Computed tomography scans (CT scans) are used to detect aneurysms and to confirm x-ray results. Ventilation-perfusion scanning is used to rule out **pulmonary embolism**. The doctor may also order an angiogram to rule out pulmonary **embolism**, or to locate a source of bleeding that could not be seen with the bronchoscope.

WWW.BOOKBAZ.IR

KEY TERMS

Aneurysm—A sac formed by the dilation of the wall of an artery, vein, or heart; it is filled with clotted blood or fluid.

Angiography—A technique for imaging the blood vessels by injecting a substance that is opaque to x rays.

Aspergillosis—A lung infection caused by the mold *Aspergillus fumigatus*.

Intubation—The insertion of a tube into a body canal or hollow organ, as into the trachea or stomach.

Pulmonary embolism—The blocking of an artery in the lung by a blood clot.

In spite of the number of diagnostic tests, the cause of hemoptysis cannot be determined in 20–30% of cases.

Treatment

Massive hemoptysis is a life-threatening emergency that requires treatment in an intensive care unit. The patient will be intubated (the insertion of a tube to help breathing) to protect the airway, and to allow evaluation of the source of the bleeding. Patients with lung cancer, bleeding from an aneurysm (blood clot), or persistent traumatic bleeding require chest surgery.

Patients with tuberculosis, **aspergillosis**, or bacterial **pneumonia** are given **antibiotics**.

Foreign objects are removed with a bronchoscope.

If the cause cannot be determined, the patient is monitored for further developments.

Prognosis

The prognosis depends on the underlying cause. In cases of massive hemoptysis, the mortality rate is about 15%. The rate of bleeding, however, is not a useful predictor of the patient's chances for recovery.

Hemorrhagic fevers

Definition

Hemorrhagic fevers are caused by viruses that produce early symptoms of muscle aches and **fever** and progress to anything from a mild illness to a potentially fatal disease. In severe cases, a prominent symptom is bleeding, or hemorrhaging, from orifices and internal organs.

Description

Although hemorrhagic fevers are regarded as **emerging diseases**, they probably have existed for many years. They are most common in tropical areas. The viruses that cause hemorrhagic fevers are maintained in nature in arthropod (insects, spiders, and other invertebrates with external hard skeletons) or other animal populations. These species serve as disease reservoirs because individuals within these populations become infected with a virus but do not die. In many cases, animals in the disease reservoir do not even develop symptoms. The viruses can then be transmitted from the reservoir population to humans by vectors—either members of the reservoir population or an intervening species, such as mosquitoes.

Hemorrhagic fevers are generally either endemic (native to a certain area) or linked to specific locations. If many people live in an endemic area, the number of cases may soar. For example, **dengue fever**, a type of hemorrhagic fever, affects approximately 100 million people annually, but has a mortality rate of only about 1%. A large percentage of those infected live in densely populated Southeast Asia, an area in which the disease vector, a mosquito, thrives.

Other hemorrhagic fevers are exceedingly rare because humans rarely encounter the virus or vector. Marburg virus disease, formerly called Marburg hemorrhagic fever, has been diagnosed in only about 40 people since its discovery in 1967. **Ebola** virus disease, formerly called Ebola hemorrhagic fever, is an African hemorrhagic fever that kills almost 90% of those infected. In 2014, an outbreak of Ebola occurred in

West Africa. As of October 2014, there were 8,400 known cases and 4,033 deaths worldwide, with most of these in Liberia, Sierra Leone, and Guinea. The virus causing the outbreak appeared to be genetically closely related to the Ebola virus that caused an earlier outbreak in Gabon and Republic of the Congo.

The onset of hemorrhagic fevers may be sudden or gradual, but all of hemorrhagic viruses have potential to stimulate hemorrhaging. However, not all cases progress to this very serious symptom. Hemorrhaging is generally attributable to the destruction of blood coagulation factors or to increased permeability of blood vessels. The severity of bleeding ranges from petechiae, which are pinpoint hemorrhages under the skin surface, to distinct bleeding from such body orifices as the nose or vagina.

Causes and symptoms

The viruses that cause hemorrhagic fevers are found most commonly in tropical locations; however, some are found in cooler climates. Typical disease vectors include rodents, ticks, or mosquitoes, bats and monkeys; person-to-person transmission in health care settings or through sexual contact can also occur.

Filoviruses

Ebola virus is the most famous of the Filoviridae, a virus family that also includes the Marburg virus. Ebola is endemic to Africa, particularly the Republic of the Congo and Sudan; the Marburg virus is found in sub-Saharan Africa. The natural reservoir of filoviruses is unknown. The incubation period, or time between infection and appearance of symptoms, is thought to last three to eight days, possibly longer.

Symptoms appear suddenly, and include severe **headache**, fever, chills, muscle aches, malaise, and appetite loss. These symptoms may be accompanied by nausea, **vomiting**, **diarrhea**, and abdominal **pain**. Victims become apathetic and disoriented. Severe bleeding commonly occurs from the gastrointestinal tract, nose and throat, and vagina. Other bleeding symptoms include petechiae and oozing from injection sites. Ebola is fatal in about 50% of cases.

Arenaviruses

Viruses of the Arenaviridae family cause Argentinean, Brazilian, Bolivian, and Venezuelan hemorrhagic fevers. Lassa fever, which occurs in West Africa, also is caused by an arenavirus. Infected rodents, the natural reservoir, shed virus particles in their urine and saliva, which humans may inhale or otherwise come in contact with.

Fever, muscle aches, malaise, and appetite loss gradually appear one to two weeks after infection with the South American viruses. Initial symptoms are followed by headache, back pain, **dizziness**, and gastrointestinal upset. The face and chest appear flushed and the gums begin to bleed. In about 30% of cases, the disease progresses to bleeding under the skin and from the mucous membranes and/or to effects on the nervous system, such as **delirium**, **coma**, and convulsions. Untreated, South American hemorrhagic fevers have a 10–30% fatality rate.

Lassa fever also begins gradually, following an 8–14 day incubation. Initial symptoms resemble those of the South American hemorrhagic fevers, followed by a **sore throat**, muscle and joint pain, severe headache, pain in the chest wall, and a dry **cough**. The face and neck become swollen, and fluid may accumulate in the lungs. Bleeding occurs in 15–20% of infected individuals, mostly from the gums and nose. Overall, the fatality rate is lower than 2%, but hospitals may encounter 20% fatality rates, treating typically the most serious of cases.

Flaviviruses

The Flaviviridae family includes the viruses that cause yellow and dengue fevers.

Yellow fever occurs in tropical areas of the Americas and Africa and is transmitted from monkeys to humans by mosquitoes. The virus may produce a mild, possibly unnoticed illness, but some individuals are suddenly stricken with a fever, weakness, **low back pain**, muscle pain, nausea, and vomiting. This phase lasts one to seven days, after which the symptoms recede for one to two days. Symptoms then return with greater intensity, along with **jaundice**, delirium, seizures, stupor, and coma. Bleeding occurs from the mucous membranes and under the skin surface, and dark blood appears in stools and vomit.

Mosquitoes also transmit the dengue virus. Dengue fever is endemic in Southeast Asia and areas of the Americas. Cases have also been reported in the Caribbean, Saudi Arabia, northern Australia, and along the border between Texas and Mexico in the United States. In 2010, 27 cases were confirmed in Key West, Florida. This virus causes either the mild dengue fever or the more serious dengue hemorrhagic fever–dengue shock syndrome (DHF-DSS).

In children, dengue fever is characterized by a sore throat, runny nose, slight cough, and a fever lasting for

WWW.BOOKBAZ.IR

a week or less. Older children and adults experience more severe symptoms: fever, headache, muscle and joint pain, loss of appetite, and a rash. The skin appears flushed, and intense pain occurs in the bones and limbs. After nearly a week, the fever subsides for one to two days before returning. Minor hemorrhaging, such as from the gums, or more serious gastrointestinal bleeding may occur.

DHF-DSS primarily affects children younger than 15 years. The symptoms initially resemble those of dengue fever in adults, without the bone and limb pain. As the fever begins to abate, the individual's condition worsens and hemorrhaging occurs from the nose, gums, and injection sites. Bleeding is also seen from the gastrointestinal, genitourinary, and respiratory tracts.

Bunyaviruses

The Bunyaviridae family includes several hundred viruses, but only a few are responsible for hemorrhagic fevers in humans.

Rift Valley fever is caused by the phlebovirus, found in sub-Saharan Africa and the Nile Delta. Natural reservoirs are wild and domestic animals, and transmission occurs through contact with infected animals or through mosquito bites. The incubation period lasts 3–12 days. Most cases of Rift Valley fever are mild and may be symptomless. If symptoms develop, they include fever, backache, muscle and joint pain, and headache. Hemorrhagic symptoms occur rarely, while death, which occurs in fewer than 3% of cases, is attributable to massive liver damage.

Crimean-Congo hemorrhagic fever is caused by nairovirus and occurs in central and southern Africa, Asia, Eurasia, and the Middle East. The virus is found in hares, birds, ticks, and domestic animals and may be transmitted by ticks or by contact with infected animals. The nairovirus incubation period is 3–12 days, after which an individual experiences fever, chills, headache, severe muscle pain, pain above the stomach, nausea, vomiting, and appetite loss. Bleeding under the skin and gastrointestinal and vaginal bleeding may develop in the most severe cases. Death rates range from 10% in southern Russia to 50% in parts of Asia.

Hantaviruses can also cause hemorrhagic fever, including the Hantaan, Seoul, Puumala, and Dobrava strains. Hantaan virus occurs in northern Asia, the Far East, and the Balkans; Seoul virus is found worldwide; Puumala virus is found in Scandinavia and northern Europe; while Dobrava virus occurs in the Balkans. Wild rodents are the natural reservoirs and transmit the virus via their excrement or body fluids or through direct contact. A hantavirus called Sin Nombre virus (SNV) is found in the western United States and western Canada. Its reservoir is the deer mouse. This variation of hantavirus was recognized in 1993 when an outbreak occurred on the Navajo reservation. Cases were reported in Yosemite National Park in California in 2012. Hantavirus diseases are also found Central and South America.

Initial symptoms develop within 10–40 days and include fever, headache, muscle pain, and dizziness. Other symptoms are blurry vision, abdominal and back pain, nausea, and vomiting. High levels of protein in the urine signal kidney damage; hemorrhaging may also occur. Death rates range up to 10%.

Diagnosis

Diagnosis begins with obtaining a history of known exposure to a certain virus, travel, contact with animals, a **physical examination**, then suitable tests. Since the hemorrhagic fevers share symptoms with many other diseases, positive identification of the disease relies on evidence of the viruses in the bloodstream by detection of antigens and antibodies or **isolation** of the virus from the body. Disruptions in the normal levels of bloodstream components may be helpful in determining some, but not all, hemorrhagic fevers.

Treatment

Lassa fever, and possibly other hemorrhagic fevers, respond to ribavirin, an antiviral medication. But as of October 2014, regarding Ebola, drug research was focused on experimental drugs and attempts at **transfusion** of serum from those who survived the same infection. Blood transfusions may be effective in lessening or stopping hemorrhage in some cases. Success with an experimental drug was achieved with the first two cases in the U.S. aid workers who contracted Ebola in West Africa and were returned to the United States for treatment. A subsequent case in the United States of an infected man returning from Liberia was fatal.

Prognosis

Recovery from some hemorrhagic fevers is more certain than from others. The filoviruses are among the most lethal; fatality rates for Ebola range from 30–90%, whereas DHF-DSS cases result in a 1–5% fatality rate. Whether a case occurs during an epidemic or as an isolated case also has a bearing on the outcome. For example, isolated cases of yellow fever have a 5% mortality rate, but 20–50% of epidemic cases may be fatal. Mortality rate is also affected by the availability

KEY TERMS

Antibody—A molecule created by the body's immune system to combat a specific infectious agent, such as a virus or bacteria.

Antigen—A specific feature, such as a protein, on an infectious agent. Antibodies use this feature as a means of identifying infectious intruders.

Coagulating factors—Components within the blood that help form clots.

Endemic—Referring to a specific geographic area in which a disease may occur.

Hemorrhage—As a noun, this refers to the point at which blood is released. As a verb, this refers to bleeding.

Incubation—The time between exposure to an infectious agent, such as a virus or bacteria, and the appearance of symptoms of illness.

Petechiae—Pinpoint hemorrhages that appear as reddish dots beneath the surface of the skin.

Reservoir—A population in which a virus is maintained without causing serious illness to the infected individuals.

Ribavirin—A drug that is used to combat viral infections.

Vector—A member of the reservoir population or an intervening species that can transmit a virus to a susceptible victim. Mosquitoes are common vectors, as are ticks and rodents.

of medical care. Many of these viruses are endemic to developing countries and rural areas where hospital care is not easily available.

Permanent disability can occur with some types of hemorrhagic fever. About 10% of severely ill Rift Valley fever patients develop retina damage and may be permanently blind, and 25% of patients with South American hemorrhagic fever develop potentially permanent deafness.

Proper treatment is vital. In cases of DHF-DSS, fatality can be reduced from 40–50% to less than 2% with adequate medical care. For individuals who survive hemorrhagic fevers, prolonged convalescence is usually inevitable. However, survivors seem to gain lifelong immunity against the virus that made them ill.

Prevention

Hemorrhagic fevers can be prevented through vector control and personal protection measures. Attempts have been made in urban and settled areas to destroy mosquito and rodent populations. In areas where such measures are impossible, individuals can use insect repellents, mosquito netting, and other methods to minimize exposure.

Vaccines have been developed against yellow fever, Argentinean hemorrhagic fever, and Crimean-Congo hemorrhagic fever. Vaccines against other hemorrhagic fevers are being researched. Another possible preventive measure is increasing the number of natural killer (NK) cells in the body. These cells appear to be an important innate source of protection against Ebola and other filoviruses.

Prevention of epidemics of hemorrhagic fevers has acquired a new importance from concern that certain causative viruses could be used as weapons of bioterrorism. These viruses could be transmitted in aerosol form as well as having a high mortality rate.

Hemorrhoids

Definition

Hemorrhoids are enlarged veins in the anus or lower rectum. They often go unnoticed and usually clear up after a few days, but can cause long-lasting discomfort, bleeding and excruciatingly **pain**. Effective medical treatments are available.

Demographics

Hemorrhoids are a very common medical complaint. More than 75% of Americans have hemorrhoids at some point in their lives, typically after age 30. Pregnant women often develop hemorrhoids, but the condition usually clears up after **childbirth**. Men are more likely than women to develop hemorrhoids that require professional medical treatment.

Clinical photo of a thrombosed external hemorrhoid. *(Custom Medical Stock Photo, Inc.)*

Description

Hemorrhoids (also called piles) can be divided into two kinds, internal and external. Internal hemorrhoids lie inside the anus or lower rectum, beneath the anal or rectal lining. External hemorrhoids lie outside the anal opening. Both kinds can be present at the same time.

Causes and symptoms

Precisely why hemorrhoids develop is unknown. Researchers have identified a number of reasons to explain hemorrhoidal swelling, including the simple fact that people's upright posture places a lot of pressure on the anal and rectal veins. **Aging**, **obesity**, **pregnancy**, chronic **constipation** or **diarrhea**, excessive use of **enemas** or **laxatives**, straining during bowel movements, and spending too much time on the toilet are considered contributing factors. Heredity may also play a part in some cases. There is no reason to believe that hemorrhoids are caused by jobs requiring, for instance, heavy lifting or long hours of sitting, although activities of that kind may make existing hemorrhoids worse.

The most common symptom of internal hemorrhoids is bright red blood in the toilet bowl or on one's feces or toilet paper. When hemorrhoids remain inside the anus they are almost never painful, but they can prolapse (protrude outside the anus) and become irritated and sore. Sometimes, prolapsed hemorrhoids move back into the anal canal on their own or can be pushed back in, but at other times they remain permanently outside the anus until treated by a doctor.

Small external hemorrhoids usually do not produce symptoms. Larger ones, however, can be painful and interfere with cleaning the anal area after a bowel movement. When, as sometimes happens, a blood clot forms in an external hemorrhoid (creating what is called a thrombosed hemorrhoid), the skin around the anus becomes inflamed and a very painful lump develops. On rare occasions the clot will begin to bleed after a few days and leave blood on the underwear. A thrombosed hemorrhoid will not cause an **embolism**.

Diagnosis

Diagnosis begins with a visual examination of the anus, followed by an internal examination during which the doctor carefully inserts a gloved and lubricated finger into the anus. The doctor may also use an anoscope, a small tube that allows him or her to see into the anal canal. Under some circumstances the doctor may wish to check for other problems by using a sigmoidoscope or colonoscope, a flexible

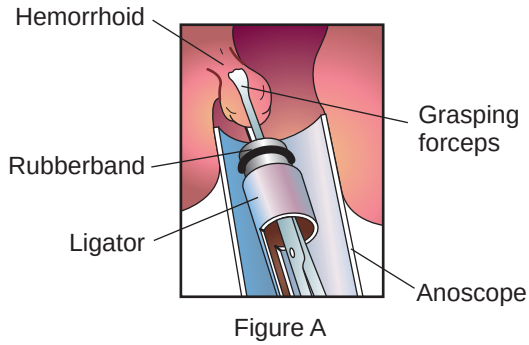

Figure A

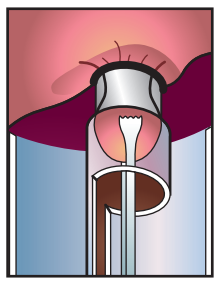

Figure B

Rubber band ligation is probably the most widely used treatment for internal hemorrhoids. An applicator is used to place one or two small rubber bands around the base of the hemorrhoid, cutting off its blood supply (figures A and B). After 3-10 days, the rubber bands and the hemorrhoid fall off, leaving a scab which disappears within a week or two. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

instrument that allows inspection of the lower colon (in the case of the sigmoidoscope) or the entire colon (in the case of the colonoscope).

Treatment

Hemorrhoids can often be effectively dealt with by dietary and lifestyle changes. Softening the feces and avoiding constipation by adding fiber to one's diet is important because hard feces lead to straining during defecation. Fruit, leafy vegetables, and whole-grain breads and cereals are good sources of fiber, as are bulk laxatives and fiber supplements, such as Metamucil or Citrucel. Exercising, losing excess weight, and drinking six to eight glasses a day of water or another liquid (not alcohol) also helps. Soap or toilet paper that is perfumed may irritate the anal area and should be avoided, as should excessive cleaning, rubbing, or wiping of that area. Reading in the bathroom is considered a bad idea, because it adds to the time one spends on the toilet and may increase the strain placed on the anal and rectal veins. After each bowel movement, wiping with a moistened tissue or pad sold for that purpose helps lessen irritation. Hemorrhoid pain is often eased by sitting in a tub of warm water for about 10 or 15 minutes two to four times a day (**sitz bath**). A cool compress or ice pack to reduce swelling is also recommended (the ice pack should be wrapped in a cloth or towel to prevent direct contact with the skin). Many people find that over-the-counter hemorrhoid creams and foams bring relief, but these medications do not make hemorrhoids disappear.

When painful hemorrhoids do not respond to home-based remedies, professional medical treatment is necessary. The choice of treatment depends on the type of hemorrhoid, what medical equipment is available, and other considerations.

Rubber band ligation is probably the most widely used of the many treatments for internal hemorrhoids (and the least costly for the patient). This procedure is performed in the office of a family doctor or specialist or in a hospital on an outpatient basis. An applicator is used to place one or two small rubber bands around the base of the hemorrhoid, cutting off its blood supply. After 3–10 days in the bands, the hemorrhoid falls off, leaving a sore that heals in a week or two. Because internal hemorrhoids are located in a part of the anus that does not sense pain, anesthetic is unnecessary and the procedure is painless in most cases. Although there can be minor discomfort and bleeding for a few days after the bands are applied, complications are rare and most people are soon able to return to work and other activities. If more than one hemorrhoid exists or if banding is not entirely effective the first time (as occasionally happens), the procedure may need to be repeated a few weeks later. After five years, 15–20% of patients experience a recurrence of internal hemorrhoids, but in most cases all that is needed is another banding.

External hemorrhoids, and some prolapsed internal hemorrhoids, are removed by conventional surgery in a hospital. Depending on the circumstances, this requires a local, regional, or general anesthetic. Surgery does cause a fair amount of discomfort, but an overnight hospital stay is usually not necessary. Full healing takes two to four weeks, but most people are able to resume normal activities at the end of a week. Hemorrhoids rarely return after surgery.

Alternatives

Like mainstream practitioners, alternative practitioners stress the importance of a high-fiber diet. To

WWW.BOOKBAZ.IR

KEY TERMS

Anus—The opening at the lower end of the rectum. The anus and rectum are both part of the large intestine, a digestive system organ.

Colon—The major part of the large intestine, a digestive system organ.

Defecation—Passage of feces through the anus.

Embolism—Obstruction of blood flow in an artery by a blood clot or other substance arising from another site. An untreated embolism can endanger health and even cause death.

Enema—The introduction of water or another liquid into the bowels through a tube inserted into the anus. Enemas are used to treat constipation and for other purposes.

Feces—Undigested food and other waste that is eliminated through the anus; also called stools.

Rectum—The lower section of the large intestine, a digestive system organ. After food has passed through the stomach and intestines and been digested, the leftover material, in the form of feces, enters the rectum, where it stays until defecation.

Suppository—A medicinal substance that slowly dissolves after being inserted into the rectum (or other body cavity).

prevent hemorrhoids by strengthening the veins of the anus, rectum, and colon, they recommend blackberries, blueberries, cherries, vitamin C, butcher's broom (*Ruscus aculeatus*), and flavonoids (plant pigments found in fruit and fruit products, tea, and soy). Herbal teas, ointments, and suppositories, and other kinds of herbal preparations, are suggested for reducing discomfort and eliminating hemorrhoids. In particular, pilewort (*Ranunculusficaria*), applied in an ointment or taken as a tea, can reduce the pain of external hemorrhoids. **Acupuncture**, **acupressure**, **aromatherapy**, and homeopathy are also used to treat hemorrhoids.

Prognosis

Hemorrhoids do not cause cancer and are rarely dangerous or life threatening. Most clear up after a few days without professional medical treatment. However, because colorectal cancer and other digestive system diseases can cause anal bleeding and other hemorrhoid-like symptoms, people should always consult a doctor when those symptoms occur.

Prevention

A high-fiber diet and the other lifestyle changes recommended for coping with existing hemorrhoids help to prevent hemorrhoids. Not straining during bowel movements is essential.

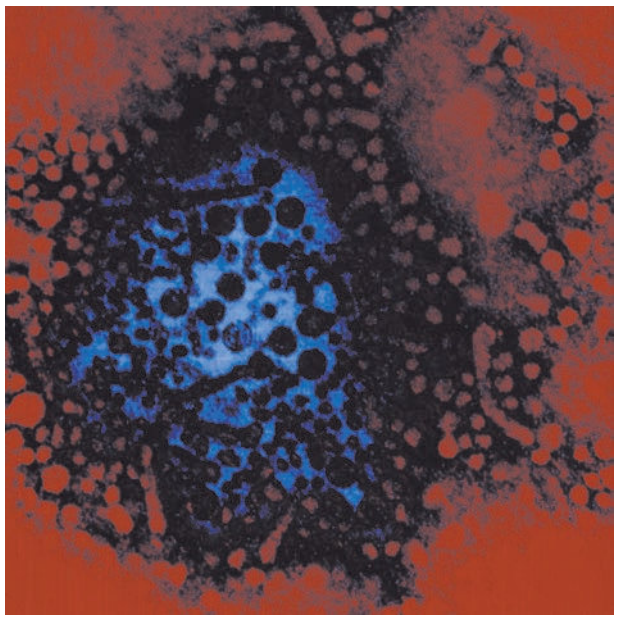
Hepatitis A

Definition

Hepatitis A is an **infectious disease** of the liver caused by the HAV virus. The disease is usually transmitted by food or water contaminated by human wastes containing the virus or by close human contact. As far as is known, only humans can get hepatitis A; it is not carried by other animals.

Hepatitis A was previously known as infectious hepatitis because it spread relatively easily from those infected to close household contacts.



Hepatitis A virus magnified 225,000 times. *(Custom Medical Stock Photo, Inc.)*

Demographics

Hepatitis A is much more common in Africa, Asia, and South America than in the United States. The rates of hepatitis A in North America have been steadily dropping since the 1980s due to improvements in **public health** policies and sanitation; on the other hand, the rates of hepatitis A among frequent travelers have been rising during the same time period.

In 1988 the Centers for Disease Control and Prevention (CDC) reported 32,000 cases in the United States; in 2003, 7653 cases were reported. The CDC estimates that nearly 25,000 people contracted hepatitis A in the United States in 2007, although the number of reported cases is much lower because many people do not show symptoms of the disease. In developing countries, children below age 2 account for most new cases of hepatitis A; in the United States, the age group most often affected is children between the ages of 5 and 14.

The states with the highest incidence of hepatitis A account for 50% of the reported cases. According to the American Academy of Pediatrics, 11 states have a rate of HAV infection that is at least twice the national average, or 20 cases per every 100,000 people. The states are Arizona, Alaska, California, Idaho, Nevada, New Mexico, Oklahoma, Oregon, South Dakota, Utah, and Washington.

Males and females are equally likely to get hepatitis A, as are people from all races and ethnic groups in the United States.

Description

Hepatitis A is an inflammation of the liver caused by the HAV virus, also called enterovirus 72, which was first identified in 1973. It differs from **hepatitis B** and **hepatitis C** in that it does not cause long-term liver damage. Even though people can take several weeks or months to recover completely from hepatitis A, they have lifelong immunity afterward. Complications from hepatitis A are rare and usually limited to people with chronic **liver disease** or those who have received a liver transplant.

Hepatitis A varies in severity, running an acute course, generally starting 2–6 weeks after contact with the virus, and lasting no longer than two or three months. Children and younger adults may have no symptoms at all, although they can still spread the disease. In general, adults are more likely to have noticeable symptoms than children or teenagers. The most common symptom is loss of energy and overall tiredness.

Some people develop a mild flu-like illness with **diarrhea**, low-grade **fever**, nausea, **vomiting**, and **muscle cramps**. People with more severe symptoms may have **pain** in the abdomen in the area of the liver (below the rib cage on the right side of the body); they may notice that their urine has turned dark brown or that they have jaundice—yellowing of the skin and the whites of the eyes. Some have an itchy skin rash.

HAV may occur in single cases after contact with an infected relative or sex partner. Alternately, epidemics may develop when food or drinking water is contaminated by the feces of an infected person. In the public's mind, outbreaks of hepatitis A usually are linked with the eating of contaminated food at a restaurant. It is true that food-handlers, who may themselves have no symptoms, can start an alarming, widespread epidemic. Many types of food can be infected by sewage containing HAV, but such shellfish as clams and oysters are common culprits.

Most people diagnosed with hepatitis A feel better 4–6 weeks after the symptoms begin, although about 15% of patients may take up to 9 months to regain their energy and feel normal again.

Risk factors

Some people are at increased risk of hepatitis A, including:

- People who travel to parts of the world with high rates of the disease and poor sanitation, including the Middle East, South America, Eastern Europe,

WWW.BOOKBAZ.IR

KEY TERMS

Antibody—A substance made by the body in response to a foreign body, such as a virus, which is able to attack and destroy the invading virus.

Antiemetic—A type of drug given to control nausea and vomiting.

Bile—A yellow-green fluid secreted by the liver that aids in the digestion of fats.

Contamination—The process by which an object or body part becomes exposed to an infectious agent such as a virus.

Epidemic—A situation where a large number of infections by a particular agent, such as a virus, develops in a short time. The agent is rapidly transmitted to many individuals.

Hepatitis—The medical term for inflammation of the liver. It can be caused by toxic substances or alcohol as well as infections.

Immune globulin—A preparation of antibodies that can be given before exposure for short-term protection against hepatitis A and for persons who have already been exposed to hepatitis A virus. Immune globulin must be given within two weeks after exposure to hepatitis A virus for maximum protection.

Incubation period—The interval from initial exposure to an infectious agent, such as a virus, and the first symptoms of illness.

Jaundice—A yellowish discoloration of the skin and whites of the eyes caused by increased levels of bile pigments from the liver in the patient's blood.

Relapse—A temporary recurrence of the symptoms of a disease.

Vaccine—A substance prepared from a weakened or killed microorganism that, when injected, helps the body to form antibodies that will prevent infection by the natural microorganism.

Mexico and Central America, Africa, Southeast Asia, and the Caribbean.

- Male homosexuals.
- People who use illicit drugs, whether injected or taken by mouth.
- Medical researchers and laboratory workers who may be exposed to HAV.
- Child care workers and children in day care centers. Children at day care centers make up an estimated 14–40% of all cases of HAV infection in the United States. Changing diapers transmits infection through fecal-oral contact. Toys and other objects may remain contaminated for some time. Often a child without symptoms brings the infection home to siblings and parents.
- Troops living under crowded conditions at military camps or in the field.
- Homeless people.

Causes and symptoms

Causes

Hepatitis A is caused by a virus that is transmitted by close personal contact with an infected person, by needle sharing, and by eating food or drinking water contaminated by fecal matter. After the virus enters the body, it multiplies in the cells of the liver, causing inflammation of the liver and a general response from the immune system that leads to most of the symptoms of the illness.

The HAV virus is shed from the liver into the bile (a digestive fluid secreted by the liver) and then into the person's stools 15–45 days before symptoms appear. That means that people can spread the virus through their feces before they know that they are sick. In the United States, hepatitis A is most commonly spread by food handlers who do not wash their hands properly after using the bathroom; by childcare workers who do not wash their hands after changing a baby's diaper; by anal sex; and by eating raw shellfish harvested from sewage-polluted waters. In very rare cases the virus can be transmitted through blood transfusions.

Symptoms

Often the first symptoms to appear are **fatigue** and general achiness. Those who like to drink coffee or smoke cigarettes may lose their taste for them. The liver often enlarges, causing pain or tenderness in the right upper part of the abdomen. As many as three out of four children have no symptoms of HAV infection, but about 85% of adults will have symptoms.

In addition to fatigue, the most common symptoms of hepatitis A include:

- Low-grade fever (101°F)
- Nausea, vomiting, and diarrhea

- Loss of appetite and weight loss
- Swelling of the liver and pain in the area of the abdomen over the liver
- Tea- or coffee-colored urine
- Jaundice
- An itchy rash or a generalized sensation of itching
- Pale or clay-colored stools
- Muscle pains

Diagnosis

Diagnosis of hepatitis A is made on the basis of the patient's history, findings during an office examination, and a blood test for HAV.

Examination

The doctor may suspect that a patient has hepatitis A during a **physical examination** in the office by feeling the area over the liver for signs of swelling and pain; taking the patient's temperature; and checking the skin and eyes for signs of **jaundice**.

Tests

A definite diagnosis is provided by a blood test for antibodies to the HAV virus. There is a specific antibody called hepatitis A IgM antibody that develops when HAV is present in the body. This test always registers positive when a patient has symptoms and should continue to register positive for four to six months. Hepatitis A IgM antibody will persist lifelong in the blood and is protective against reinfection.

In some cases the doctor may also have the sample of blood checked for abnormally high levels of liver enzymes.

Treatment

Traditional

There is no specific drug treatment for hepatitis A, as **antibiotics** cannot be used to treat virus infections. Most people can care for themselves at home by making sure they get plenty of fluids and adequate **nutrition**. People whose appetite has been affected may benefit from eating small snacks throughout the day rather than three main meals and by eating soft and easily digested foods.

Patients with hepatitis A should avoid drinking alcohol, which makes it harder for the liver to recover from inflammation. Patients should also tell their doctor about any over-the-counter or prescription drugs they are taking because the drugs may need to be stopped temporarily or have the dosages changed.

Drugs

Patients with hepatitis A may take **acetaminophen** to reduce fever and relieve pain. Patients with mild vomiting may be prescribed **antiemetics** (drugs to control nausea); the drug most commonly prescribed for hepatitis patients is metoclopramide (Reglan). Those with severe vomiting may need to be hospitalized in order to receive intravenous fluids.

Prognosis

Most people recover fully from hepatitis A within a few weeks or months. Between 3% and 20% have relapses (temporary recurrences of symptoms) for as long as six to nine months after infection. In the United States, serious complications are infrequent and deaths are very rare. As many as 75% of adults over 50 years of age in North America will have blood test evidence of previous hepatitis A.

About 1% of patients develop liver failure following HAV infection, mostly those over age 60 or those with chronic liver disease. In these cases **liver transplantation** may be necessary for the patient's survival. There are about 100 deaths from hepatitis A reported each year in the United States.

Prevention

Hepatitis A can be prevented by a vaccine called Havrix that is given before exposure to the HAV virus. The vaccine is given in two shots, the second given between 6 and 18 months after the first. It confers immunity against hepatitis A for at least 20 years. Those who should receive the vaccine include people in the military and those who travel abroad frequently; men who have sex with other men; people who use intravenous drugs; people with **hemophilia** who must receive human blood products; and people who have chronic hepatitis B or C infection.

People who have been exposed to the HAV virus should be given immune globulin to protect them against getting sick, because Havrix is not effective in people who have already been exposed to HAV. Children under the age of 2 should be given immune globulin or a vaccine called Epaxal that was introduced in 2007 rather than Havrix to protect them against HAV.

A vaccine against hepatitis A introduced in 2007 is called Epaxal; there is a version for children called Epaxal Junior that appears to be a good choice for

WWW.BOOKBAZ.IR

mass **vaccination** programs. Unlike Havrix, Epaxal Junior can be given to children above the age of one year.

The risk of hepatitis A can be reduced by observing the following precautions:

- Practice good personal hygiene; wash hands frequently, especially after using the toilet or changing a child's diaper.
- When traveling, drink only bottled water; avoid raw or undercooked meat or shellfish; and avoid eating fresh fruits or vegetables unless you have washed and peeled them yourself.
- Avoid sharing drinking glasses and eating utensils. If someone in the family has hepatitis A, wash their glasses and utensils separately in hot, soapy water.
- Avoid sexual contact with anyone who has hepatitis A.

Hepatitis, alcoholic

Definition

Alcoholic hepatitis is an inflammation of the liver caused by alcohol.

Description

Irritation, whether from toxins or infections, causes a similar response in body organs. The response is known as inflammation and consists of:

- an increase in the blood to the affected organ

- redness and swelling of the organ
- influx of immune agents like white blood cells and their arsenal of chemical weapons
- pain

As the acute process subsides, there is either healing or lingering activity. Lingering activity—chronic disease—has a milder presentation with similar ingredients. Healing often takes the form of scarring, wherein normal functioning tissue is replaced by tough, fibrous, and non-productive scar tissue. Both chronic disease and healing can happen simultaneously, so that scar tissue progressively replaces normal tissue. This leads to **cirrhosis**, a liver so scarred it is unable to do its job adequately.

Alcohol can cause either an acute or a chronic disease in the liver. The acute disease can be severe, even fatal, and can bring with it hemolysis—blood cell destruction. Alcohol can also cause a third type of **liver disease**, **fatty liver**, in which the continuous action of alcohol turns the liver to useless fat. This condition eventually progresses to cirrhosis if the poisoning continues.

Causes and symptoms

Inflammation of the liver can be caused by a great variety of agents—poisons, drugs, viruses, bacteria, protozoa, and even larger organisms like worms. Alcohol is a poison if taken in more than modest amounts. It favors destroying stomach lining, liver, heart muscle, and brain tissue. The liver is a primary target because alcohol travels to the liver after leaving the intestines. Those who drink enough to get alcohol **poisoning** have a tendency to be undernourished, since alcohol provides ample calories but little **nutrition**. It is suspected that both the alcohol and the poor nutrition produce alcoholic hepatitis.

Diagnosis

Hepatitis of all kinds causes notable discomfort, loss of appetite, nausea, **pain** in the liver, and usually **jaundice** (turning yellow). Blood test abnormalities are unmistakably those of hepatitis, but selecting the precise cause may take additional diagnostic work.

Treatment

As with all poisonings, removal of the offending agent is primary. There is no specific treatment for alcohol poisoning. General supportive measures must see the patient through until the liver has healed by itself. In the case of fulminant (sudden and severe) disease, the liver may be completely destroyed and have to be replaced by a transplant.

KEY TERMS

Cirrhosis—Disruption of normal liver structure and function caused by any type of chronic disease such as hepatitis and alcohol abuse.

Fatty liver—An abnormal amount of fat tissue in the liver caused by alcohol abuse.

Hemolysis—Disintegration of red blood cells.

Protozoa—One-celled microscopic organisms like amoeba.

Prognosis

The liver is robust. It can heal without scarring after one or a few episodes of hepatitis that resolve without lingering. It can, moreover, regrow from a fragment of its former self, provided there is not disease or poison still inhibiting it.

Prevention

Alcohol is lethal in many ways when ingested in excess. Research suggests that the maximum healthy dose of alcohol per day is roughly one pure ounce—the amount in two cocktails, two glasses of wine, or two beers.

Hepatitis, autoimmune

Definition

A form of liver inflammation in which the body's immune system attacks liver cells.

Description

Autoimmunity causes the body's defense mechanisms to turn against itself. Many of the tissues in the

WWW.BOOKBAZ.IR

KEY TERMS

Allergen—Any chemical that causes an immune reaction only in people sensitive to it.

Antigen—Any chemical that can be the target of an immune response.

Biopsy—Surgical removal of a piece of tissue for examination.

Jaundice—A yellow color to the skin from bile that backs up into the circulation.

body can be the target of such an attack. While one tissue type predominates, others may be involved in a general misdirection of immune activity, perhaps because the specific target antigen is present in differing quantities in each of the affected tissues. There seem to be hereditary causes for autoimmunity, since these diseases tend to run in families and have genetic markers. Among the more common diseases believed to fall within this category are **rheumatoid arthritis**, **systemic lupus erythematosus**, **multiple sclerosis**, and **psoriasis**.

The process of autoimmune disease is very similar to **infectious disease** and allergy, so that great caution is observed in placing a disorder in this class. Germs were found to cause several diseases originally thought to be autoimmune. Allergens cause others. Many more may be uncovered. Autoimmunity is often believed to originate with a virus infection. A chemical in the virus resembles a body chemical so closely that the immune system attacks both.

Autoimmune hepatitis is similiar to viral hepatitis, a disease of the liver. It can be an acute disease that kills over a third of its victims within six months, can persist for years, or can return periodically. Some patients develop **cirrhosis** of the liver which, over time, causes the liver to cease functioning.

Causes and symptoms

Symptoms of autoimmune hepatitis resemble those of other types of hepatitis. Patients who develop autoimmune hepatitis experience **pain** under the right ribs, **fatigue** and general discomfort, loss of appetite, nausea, and sometimes **vomiting** and **jaundice**. In addition, other parts of the body may be involved and contribute their own symptoms.

Diagnosis

Extensive laboratory testing may be required to differentiate this disease from viral hepatitis. The distinction may not even be made during the initial episode. There are certain markers of autoimmune disease in the blood that can lead to the correct diagnosis if they are sought. In advanced or chronic cases a **liver biopsy** may be necessary.

Treatment

Autoimmune hepatitis is among the few types of hepatitis that can be treated effectively. Since treatment itself introduces problems in at least 20% of patients, it is reserved for the more severe cases. Up to 80% of patients improve with cortisone treatment, although a cure is unlikely. Another drug—azathioprine—is sometimes used concurrently. Treatment continues for over a year and may be restarted during a relapse. At least half the patients relapse at some point, and most will still continue to have progressive liver scarring.

If the liver fails, transplant is the only recourse.

Prognosis

In spite of treatment, autoimmune hepatitis can re-erupt at any time and may continue to damage and scar the liver. The rate of progression varies considerably from patient to patient.

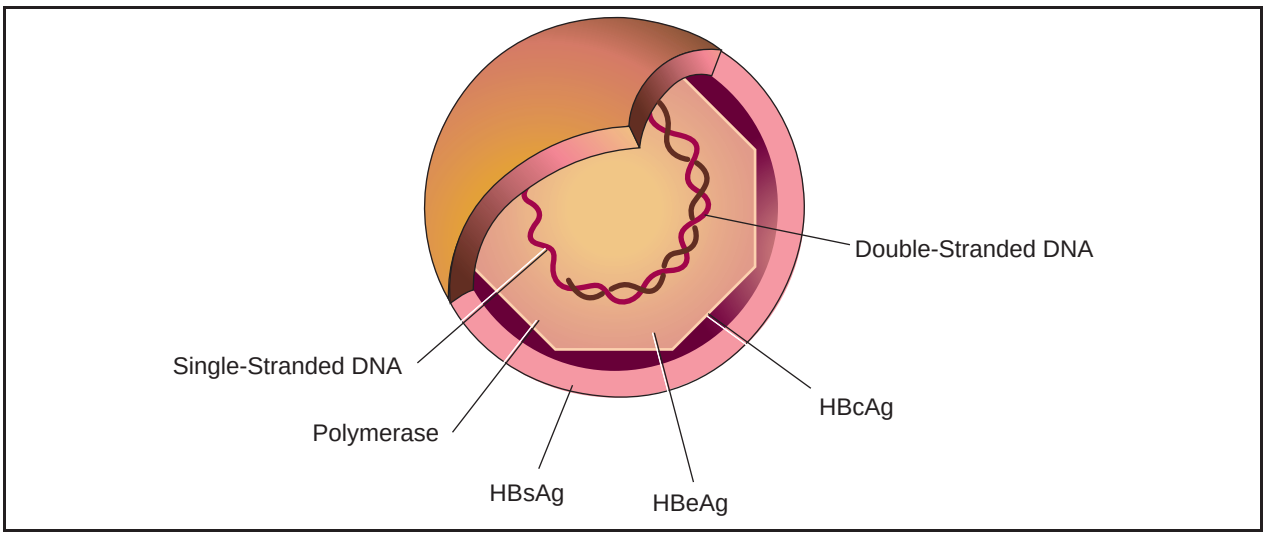
Hepatitis B

Definition

Hepatitis B is a viral infection of the liver transmitted through the blood or body fluids of someone who is infected. It is also called serum hepatitis because it can be transmitted through blood serum, the liquid portion of blood. Besides the virus that causes hepatitis B (known simply as hepatitis B virus, or HBV), other viruses can cause different types of hepatitis, including hepatitis A and hepatitis C. Vaccines are available for hepatitis A and B.

Hepatitis B is the most common serious liver infection worldwide. The disease has two forms: an



Hepatitis B virus (HBV) is composed of an inner protein core and an outer protein capsule. The outer capsule contains the hepatitis B surface antigen (HBsAg). The inner core contains HBV core antigen (HBcAg) and hepatitis B e-antigen (HBeAg). This cell also contains polymerase, which catalyzes the formation of the cell's DNA. HBV is the only hepatitis-causing virus that has DNA, instead of RNA. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

acute form that lasts a few weeks, and a chronic form that can last for years. The chronic form can lead to cirrhosis, liver failure, liver cancer, and even death. Acute hepatitis B has a 5% chance of leading to the chronic form of the infection in adults. The odds are higher in children, who have a 25–50% chance of developing chronic hepatitis B; and are even higher among infants who were infected during the mother's pregnancy. These infants have a 90% chance of developing chronic hepatitis B.

Demographics

The World Health Organization estimates that "more than 780,000 people die every year due to the acute or chronic consequences of hepatitis B." According to the Hepatitis B Foundation, more than 12 million Americans have been infected with hepatitis B, and nearly 100,000 are newly infected every year. The foundation also states that at least a million people carry the disease. Annually, more than 5,000 U.S. deaths are related to hepatitis B.

The population most commonly affected by hepatitis B in the United States includes adults between the ages of 20 and 50, however, the routine immunization of children against the disease since 1990 has led to a decline in the rate of acute hepatitis in North America. African Americans are more likely to be infected than either Hispanics or Caucasians; and a greater proportion of Alaskan Eskimos and Pacific Islanders are carriers than members of other racial groups. Asian Americans are at increased risk of severe liver damage from hepatitis B compared to members of other racial groups. More males than females are infected with hepatitis B in all races and age groups.

Description

Hepatitis B has an incubation period of 1–6 months. About 50% of people with the acute form of the disease have no symptoms at all. The other half experience loss of appetite, nausea and vomiting, and jaundice around 12 weeks after getting infected. Some patients may also have joint pain, itchy skin, or abdominal pain. Many of these patients assume that they have influenza.

Many patients with chronic hepatitis also may be symptom-free, but one-third do experience symptoms, which are like those occurring with the acute form of the disease. Between 15–25% of people with chronic hepatitis B eventually die of liver disease.

HBV is most often transmitted via direct contact, because it is a blood-borne pathogen. It is not easily transmitted indirectly, so casual contact, such as shaking hands or even sharing a workplace or a restroom with an infected person, does not expose individuals to hepatitis B. On the other hand, HBV is a durable virus that can survive outside the body for at least seven days. During that time, the virus can still cause disease if it enters the body of a person who is not infected. For that reason, it is necessary to clean any surface contaminated by blood spills carefully with a mixture

WWW.BOOKBAZ.IR

of chlorine bleach and water. This includes dried blood spills. Medical or dental instruments must be sterilized with particular care.

People who have been infected by HBV and have recovered from the infection are protected against hepatitis B for the rest of their lives. People can also receive protection via a vaccine against the disease, but to remain effective, the vaccination must be repeated every 5–10 years, as directed by a doctor.

Risk factors

Risk factors for hepatitis B include:

- Having unprotected sex with a partner regardless of sexual orientation.
- Having a large number of sexual partners.
- Being infected with another sexually transmitted disease (STD), particularly gonorrhea or chlamydia.
- Sharing needles with other intravenous drug users.
- Having a family member with chronic HBV infection.
- Having had a blood transfusion or having used blood products before 1972.
- Needing hemodialysis for kidney disease.
- Frequent traveling to parts of the world with high rates of hepatitis B. These include the Middle East, southern Africa, China, Southeast Asia, Brazil, and the Pacific Islands.
- Emigrating from or adopting a child from any of the countries listed above.
- Working in a hospital, clinic, or other facility requiring frequent exposure to blood, open wounds, or other body secretions. Healthcare workers at risk include dentists and dental hygienists, as well as physicians, nurses, and laboratory technicians.
- Working as a police officer, firefighter, or other emergency first responder.
- Being a prison inmate.
- Living or working in a facility for the developmentally disabled.

Causes and symptoms

Causes

Hepatitis B is caused by HBV. HBV is the only deoxyribonucleic acid, or DNA, virus that is a major cause of hepatitis. It is made up of several fragments called antigens that stimulate the body's immune system to produce the antibodies that can neutralize or even destroy the infecting virus. It is, in fact, the immune reaction and not the virus, that seems to cause the liver inflammation associated with hepatitis All other common viruses that cause hepatitis are known as RNA viruses because they contain ribonucleic acid or RNA as their genetic material. HBV has three major antigens that draw an immune response. One is the surface antigen, which is used in the vaccination against HBV). The other two are the core antigen (HBcAg), and the e-antigen (HBeAg). Studies are currently under way to understand the exact roles of the core antigen and the e-antigen, and how the two interact, in hopes of developing a treatment for chronic hepatitis.

Hepatitis B is primarily a blood-borne infection, but it can also be transmitted through contact with the semen, vaginal secretions, or saliva of an infected person. The virus can enter the body through injection, a break in the skin, or contact with the mucous membranes that line the mouth, genitals, and rectum. Hepatitis B cannot be transmitted from food or from shaking hands, sneezing or coughing, breastfeeding, or casual contact with an infected person.

Symptoms

ACUTE HEPATITIS B. In the United States, a majority of acute HBV infections occur in teenagers and young adults. Half of this population never develops symptoms, and only about 20% of infected patients develop severe symptoms and yellowing of the skin (jaundice). Jaundice occurs when the infected liver is unable to get rid of certain colored substances, or pigments, as it normally does. The remaining 30% of patients have only "flu-like" symptoms and usually are unaware that they have hepatitis B unless they have a blood test that identifies it.

The most common symptoms of acute hepatitis B are loss of appetite, nausea, generally feeling poorly, and pain or tenderness in the right upper part of the abdomen (where the liver is located). Compared to patients with hepatitis A or C, those with symptoms from HBV infection are less able to continue their usual activities and require more time resting in bed.

Occasionally patients with HBV infection will develop joint swelling and pain (arthritis), as well as hives or a skin rash before jaundice appears. The joint symptoms usually last no longer than 3–7 days.

Typically, the symptoms of acute hepatitis B do not persist longer than two or three months. Four months is an abnormally long-lasting acute infection. In a small number of patients—fewer than 3% or so—the infection keeps getting worse as the liver cells die off. Jaundice deepens, and patients may bleed easily when the level of coagulation factors, which are normally made by the liver, decreases. They may also

experience edema, which is the collection of large amounts of fluid in the abdomen and beneath the skin.

Fewer than 1% of patients develop a severe form of hepatitis B known as fulminant hepatitis. This form of the disease appears rapidly and can cause death if not treated at once. Its symptoms include:

- sudden collapse
- mental confusion, hallucinations, or extreme sleepiness
- jaundice
- noticeable swelling of the abdomen

CHRONIC HEPATITIS B. HBV infection lasting longer than six months is said to be chronic, and it is much less likely that the infection will disappear. Most infants infected with HBV at birth and many children infected between one and five years of age become chronically infected.

Not all carriers of HBV develop chronic liver disease and, in fact, a majority of carriers have no symptoms. About one in every four HBV carriers, however, develops liver disease that gets worse over time as the liver becomes more and more scarred (a badly scarred liver is called cirrhosis) and less able to carry out its normal functions. Patients are likely to have an enlarged liver and spleen, as well as tiny clusters of abnormal blood vessels in the skin that resemble spiders. Some disease progresses to chronic end-stage liver disease (cirrhosis), which is ultimately fatal. Overall, HBV accounts for 5–10% of cases of chronic end-stage liver disease in the United States.

The most serious complication of chronic HBV infection is liver cancer. Primary liver cancer (cancer that originates in the liver) is the third leading cause of cancer deaths worldwide. The overall chance that liver cancer will develop at any time in the life of a patient with chronic hepatitis B, however, is probably much lower than 10%. Patients who drink or smoke have an increased risk for developing liver cancer.

It is not unusual for a person to be infected simultaneously by HIV (human immunodeficiency virus, the cause of AIDS) and HBV. This combination, especially in men, can increase their risk of dying from liver disease compared to people infected with just one of the diseases.

Diagnosis

Among patients who have symptoms, the doctor may observe swelling or tenderness in the right upper quadrant of the patient's abdomen; enlargement of the spleen; a low-grade fever; reddening of the palms of the hands; and signs of jaundice. If the disease has progressed to cirrhosis, the doctor may be able to detect the presence of fluid in the abdomen.

Most patients have no symptoms, and hepatitis B is identified during blood tests given as part of a routine annual health checkup. To confirm the diagnosis of hepatitis B, the doctor will take one or more blood samples for check for:

- Liver function, if this has not already been done. Abnormal liver function results are a strong indicator of hepatitis C infection.
